The tics present within Tourette syndrome are believed to be due to a hyper-dopaminergic state that is amenable to treatment by dopamine receptor antagonists. Pimozide is the only conventional antipsychotic with this indication, which is its only FDA-approved indication.

## Huntington’s Disease

Although there is no cure for Huntington’s disease, the psychosis and choreiform movements associated with this disease may be ameliorated by dopamine receptor antagonism. Several conventional antipsychotics carry FDA indications for treatment of this disease.

## Nausea, Emesis, and Hiccups

The lower-potency antipsychotics exert a potent antiemetic effect through histamine<sub>1</sub> (H<sub>1</sub>) receptor antagonism. This effect is closely related to their original role in reducing perioperative stress and emesis. Many well-known antiemetics, such as promethazine (Phenergan), are phenothiazines with a short-chain substitution. In addition, chlorpromazine is approved for oral or intramuscular therapy of intractable hiccups.

## Side Effects and Toxicology

As noted earlier, side-effect profile—rather than efficacy in treating psychosis—is used to differentiate the conventional antipsychotics (Dodd et al. 2015). These agents serve as antagonists at four major neurotransmitter receptor systems in the central nervous system (CNS): the dopamine type 2 receptor family (D<sub>2</sub>, D<sub>3</sub>, and D<sub>4</sub>), muscarinic cholinergic receptors (M<sub>1</sub>), α-adrenergic receptors (α<sub>1</sub> and α<sub>2</sub>), and histamine receptors (H<sub>1</sub>) (Table 24-1).

**TABLE 24-1. Relative affinities of classic antipsychotics to various neurotransmit**

	Chlorpromazine	Thioridazine	Perphenazine	Trifluoperazine	Fluphenazine	Th
D <sub>1</sub>	High	—	High	High	High	M
D <sub>2</sub>	High	Very high	Very high	Very high	Very high	Ve
D <sub>3</sub>	High	Very high	Unknown	Unknown	Very high	Ur
D <sub>4</sub>	High	Very high	Unknown	High	Very high	Ur
H <sub>1</sub>	High	High	Moderate	Moderate	High	M

*Note.* Receptor families: dopamine (D<sub>1</sub>, D<sub>2</sub>, D<sub>3</sub>, D<sub>4</sub>), histamine (H<sub>1</sub>), muscarinic cholinergic HT<sub>1</sub>, 5-HT<sub>2</sub>).

	Chlorpromazine	Thioridazine	Perphenazine	Trifluoperazine	Fluphenazine	Th
M <sub>1</sub>	High	High	Low	Low	Low	Lo
α <sub>1</sub>	Very high	Very high	High	High	High	M
α <sub>2</sub>	Moderate	Very high	Moderate	Low	Low	M
5-HT <sub>1</sub>	Low	Low	Low	Low	Low	Lo
5-HT <sub>2</sub>	High	High	Moderate	Moderate	Moderate	M

*Note.* Receptor families: dopamine (D<sub>1</sub>, D<sub>2</sub>, D<sub>3</sub>, D<sub>4</sub>), histamine (H<sub>1</sub>), muscarinic cholinergic HT<sub>1</sub>, 5-HT<sub>2</sub>).

The therapeutic action of classic antipsychotics in ameliorating the positive symptoms of schizophrenia is believed to be due to D<sub>2</sub> blockade in the mesolimbic dopamine tract. Blockade of D<sub>2</sub> receptors in the mesocortical, nigrostriatal, and tuberoinfundibular systems leads to the tract-related side effects described earlier in this chapter (see section “Pharmacological Profile”). Lower-potency agents have greater antihistaminergic, anticholinergic, and antiadrenergic actions. However, they have fewer D<sub>2</sub>-related side effects because of their lower affinity to D<sub>2</sub> receptors and relatively high anticholinergic activity. Higher-potency agents, such as haloperidol, produce more D<sub>2</sub>-related movement disorders and prolactin elevation but otherwise have a cleaner side-effect profile, having fewer anticholinergic, antiadrenergic, and antihistaminergic side effects. Anticholinergic action often leads to dry mouth (xerostomia), blurred vision (mydriasis), constipation, urinary retention, sinus tachycardia, confusion, impaired cognition, paralytic ileus, exacerbation of open-angle glaucoma, and drowsiness. Antagonism of α<sub>1</sub>-adrenergic receptors is associated with orthostatic hypotension, QTc prolongation, reflex tachycardia, dizziness, incontinence, and sedation. Antagonism of α<sub>2</sub> receptors can be associated with retrograde ejaculation and priapism. Antagonism of H<sub>1</sub> receptors leads to sedation, drowsiness, and weight gain.

The frequencies of adverse reactions to classic antipsychotic agents are summarized in [Table 24-2](#).

**TABLE 24-2. Incidence of adverse reactions to classic antipsychotics at therapeutic doses**

	Phenothiazines			
	Chlorpromazine	Mesoridazine	Thioridazine	Fluphenazine
<b>Cognitive effects</b>				
Drowsiness, sedation	High	High	High	Low
Insomnia, agitation	Low	Low	Low	Low
<b>Extrapyramidal effects</b>				
Parkinsonism	Low to Moderate	Low to Moderate	Low	High
Akathisia	Low	Moderate	Low	High

<b>Other effects</b>				
Blood dyscrasias	Low to Moderate	Low	Low	Low
Hepatic disorder	Low	Low	Low	Low
Seizures	Moderate	Moderate	Moderate	Low

## Cognitive Side Effects

CNS side effects of classic antipsychotics can be subclassified into cognitive and neuromuscular side effects. Cognitive effects include sedation, confusion, disturbed concentration, memory impairment, and delirium ([Himelhoch et al. 1996](#)). Antihistaminergic and anticholinergic actions lead to sedation and slowed mentation. These effects, which are most pronounced with lower-potency agents (e.g., chlorpromazine), are most severe earlier in treatment, with some tolerance developing over time. Anticholinergic delirium is the most common cause of medication-induced delirium. Because delirium results in high rates of morbidity and mortality (over 20%

mortality), this potential side effect is important, especially in populations of individuals who are more sensitive to anticholinergic medications, such as the elderly. In addition, every antipsychotic—especially the low-potency agents—can potentially lower the seizure threshold.

## Extrapyramidal Side Effects

Neuromuscular CNS side effects are due to antagonism of D<sub>2</sub> receptors in the nigrostriatal dopaminergic pathway. Generally, antipsychotics manifest EPS when dopaminergic blockade exceeds 75%–80% of D<sub>2</sub> receptors. EPS are most frequent with the high-potency agents such as haloperidol. A greater risk of EPS differentiates the classic from the atypical antipsychotics—in fact, the term *atypical* was originally coined to highlight this ability to produce an antipsychotic effect equivalent to that of the typical high-potency agents with lower EPS.

### Acute-Onset EPS

Acute-onset EPS include medication-induced parkinsonism, acute dystonia, and akathisia. *Antipsychotic-induced parkinsonism* occurs in 15% of patients after several weeks of treatment. It is more common in patients older than 40 years, although it can occur at any age. Symptoms are identical to those of Parkinson's disease and include muscle stiffness ("lead-pipe" rigidity), cogwheel rigidity, shuffling gait, stooped posture, drooling, bradykinesia, resting tremor, masked facies, and akinesia. Slowed, restricted movements of the body and face (*akinesia*) may be mistakenly diagnosed as being due to depression or the negative symptoms of schizophrenia.

It is estimated that up to 10% of patients may experience an acute dystonic episode, which usually occurs within the first few hours or days of treatment. It is more common in youth, in recent cocaine users, and with intramuscular doses of high-potency antipsychotics. *Dystonia* is an acute, sustained, painful muscular contraction. Potential areas of involvement include the tongue (protrusions, twisting), jaw, neck (spasmodic retrocollis or torticollis), and back (opisthotonos). If the dystonia involves the eyes, it results in a symmetrical or unilateral upward lateral movement called an *oculogyric crisis*. Laryngeal dystonia can result in sudden death secondary to a patient's inability to breathe. Dystonia can be extremely uncomfortable and frightening for patients and can lead to noncompliance with medication for fear of recurrence. Treatment of dystonia requires rapid diagnosis and intravenous administration of antihistaminergic or anticholinergic agents. Anticholinergic agents are often initiated with high-potency antipsychotics in an effort to avoid this side effect.

*Akathisia* is a subjective feeling of motor restlessness in which patients feel an irresistible urge to move continuously. It is described as an unpleasant sensation and may result in dysphoria. Akathisia can occur at any time during treatment and is the most prevalent of the EPS. It frequently leads to noncompliance with medications and is believed to increase suicide risk in some patients.

### Late-Onset EPS

*Tardive dyskinesia* is characterized by a persistent syndrome of involuntary choreoathetoid movements of the head, limbs, and trunk. It generally takes at least 3–6 months of exposure to antipsychotics before the disorder develops. Perioral movements involving buccolingual masticatory musculature are the most common early manifestation

of tardive dyskinesia. Tardive dyskinesia has an estimated yearly incidence of 5% among adults and as high as 25% in the elderly who receive continuous conventional antipsychotic therapy and has been a major source of litigation in past psychiatric practice. The risk of developing tardive dyskinesia is reported to increase with age and to be higher in certain ethnic groups; female gender, presence of mood disorders, and early onset of EPS have also been associated with increased risk of tardive dyskinesia.

Tardive dyskinesia may be masked by continuing dopamine blockade and has a variable course following development. Over time, spontaneous resolution or improvement has been described in some individuals. There is no single effective treatment, although treatment with clozapine has been reported to improve symptoms. Cases of tardive dyskinesia have been described with every antipsychotic, although classic antipsychotics are associated with a much greater risk of tardive dyskinesia than second-generation or atypical agents ([Correll et al. 2004](#)). Other tardive syndromes include tardive dystonia, tardive akathisia, and tardive pain.

## Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a poorly understood syndrome that usually appears within hours or days of initiation of antipsychotic treatment. This syndrome is characterized by muscular rigidity, hyperpyrexia, autonomic instability (hypo- or hypertension, tachycardia, diaphoresis, pallor), and altered consciousness. NMS has an estimated incidence of 0.02%–2% and carries a mortality rate of 20%–30%. Death most often occurs secondary to dysrhythmias, renal failure secondary to rhabdomyolysis, aspiration pneumonia, or respiratory failure. Laboratory findings include elevated creatine phosphokinase, elevated white blood cell count, elevated liver enzymes, myoglobinemia, and myoglobinuria. The syndrome can last up to 10–14 days.

Treatment requires immediate discontinuation of the offending antipsychotic and supportive care with aggressive intravenous hydration. In the past, mild cases of NMS were treated with intravenous bromocriptine, while more severe cases were treated with intravenous dantrolene. However, randomized controlled clinical trials of NMS treatment have never been performed because of its infrequent occurrence.

## Cardiac Effects

$\alpha$ -Adrenergic antagonism is associated with orthostatic hypotension with reflex tachycardia, with tolerance possibly developing later in the treatment course. Orthostasis is important because of an increase in falls and related injuries.

Recent studies involving several antipsychotics have drawn attention to the risk of cardiac dysrhythmias, which is especially prominent with use of lower-potency conventional antipsychotics. High dosage, rapid titration, intramuscular administration, and especially intravenous administration may be associated with a lengthening of the QTc interval, with resulting risk of serious dysrhythmias such as torsades de pointes and ventricular fibrillation. Studies with thioridazine have raised concerns about piperidine antipsychotics, leading to a decrease in the use of this class. In reality, *torsades de pointes* is rarely encountered during treatment with conventional antipsychotics, although some have speculated that a syndrome of unexplained sudden death described with all conventional antipsychotics may be related to sudden dysrhythmias.

## Gastrointestinal Side Effects

The anticholinergic actions of conventional agents include dry mouth, nausea, vomiting, and constipation that can progress to paralytic ileus. Antihistaminergic action is associated with medication-related weight gain, which greatly increases the patient's risk of developing diabetes.

Cholestatic jaundice is a hypersensitivity reaction described with the aliphatic phenothiazines, especially chlorpromazine (incidence of 0.1%). This reaction typically manifests during the first 1-2 months of treatment and presents with nausea, malaise, fever, pruritus, abdominal pain, and jaundice, with resulting elevations in levels of bilirubin and alkaline phosphatase. This condition rarely lasts more than 2-4 weeks after discontinuation.

## Weight Gain, Diabetes Mellitus, and Dyslipidemia

With the introduction of atypical antipsychotics, several of which cause significant weight gain, there is renewed awareness of the metabolic side effects associated with antipsychotic therapy such as obesity, elevated cholesterol and triglyceride levels, and an increased risk of diabetes mellitus. These metabolic changes increase the risk of ischemic heart disease and contribute to the increased mortality observed in schizophrenia. Antihistaminergic action is associated with medication-related weight gain, which greatly increases the patient's risk of developing diabetes. Diabetes is currently described as a worldwide epidemic. Serotonin 5-HT<sub>2C</sub> receptor blockade also significantly contributes to weight gain ([Tandon and Halbreich 2003](#)). There are significant differences among classic antipsychotics with reference to their propensity to cause these metabolic adverse effects. Molindone is the least likely to cause weight gain, whereas thioridazine and chlorpromazine are among the most likely to do so. In general, high-potency agents cause less weight gain than do low-potency agents.

## Genitourinary Side Effects

Renal effects secondary to blockade of M<sub>1</sub> receptors include urinary hesitancy or retention, which can lead to a comparable increase in urinary tract infections in both genders. As mentioned previously, antagonism of tuberoinfundibular dopaminergic tracts increases prolactin secretion. Clinical manifestations of hyperprolactinemia include gynecomastia, galactorrhea, diminished libido, erectile dysfunction, amenorrhea, decreased bone density, menstrual irregularities, infertility, delayed ovulation, and possibly increased risk of breast cancer. Other sexual side effects, such as erectile disorder, retrograde ejaculation (due to blockade of  $\alpha_2$ -adrenergic receptors), anorgasmia, and occasionally priapism, can also occur with conventional antipsychotics.

## Hematological Side Effects

Hematological effects of conventional antipsychotics include transient leukopenia (white blood cell [WBC] count  $<3,500/\text{mm}^3$ ), which is common but not usually problematic, and agranulocytosis (WBC count  $<500/\text{mm}^3$ ), a life-threatening problem. Agranulocytosis occurs most often during the first 3 months of treatment, with an incidence of 1 in

500,000. Aliphatic and piperidine phenothiazines are the most common causal agents among the conventional antipsychotics. Rarely, thrombocytopenic or nonthrombocytopenic purpura, hemolytic anemia, and pancytopenia may occur.

## Ocular Side Effects

In addition to direct anticholinergic ocular effects such as blurred vision (mydriasis and cycloplegia) and exacerbation of open-angle glaucoma, direct optic toxicity has been described. The conventional antipsychotics are associated with several kinds of optical pathology involving the lens, cornea, and retina. Lenticular opacities have been reported with some phenothiazines, including perphenazine, chlorpromazine, and thioridazine. An irreversible increase in retinal pigmentation has been described with thioridazine when high dosages (>800 mg/day) are used. This retinal pigmentation, which can progress even after drug discontinuation, can lead to reduced visual acuity and even blindness. Early symptoms include poor night vision and secondary nocturnal confusion.

## Dermatological Side Effects

Cutaneous side effects of conventional antipsychotics involve hypersensitivity rashes—most commonly maculopapular erythematous rashes of the trunk, face, neck, and extremities—and photosensitivity reactions that can lead to severe sunburn. Care must be taken with injectable versions of many antipsychotics because of direct dermatological toxicity if the skin or subcutaneous layers are exposed. Prolonged use of chlorpromazine can lead to blue-gray discoloration in body areas exposed to sunlight.

---

## Drug-Drug Interactions

---

Careful consideration of a patient's existing drug regimen should be given prior to the initiation of antipsychotic therapy.

## Protein Binding

Because conventional antipsychotics are tightly protein bound, care must be taken when these medications are administered with other highly protein-bound medications. Mutual displacement of medications such as phenytoin, digoxin, warfarin, and valproate could lead to a short-term increase in serum levels of these drugs and of the conventional antipsychotic. However, protein binding has not been of serious clinical significance.

## Cytochrome P450 Inhibition

As mentioned previously, conventional antipsychotics are primarily hepatically metabolized through the CYP2D6 and 3A4 enzymes. In addition, each inhibits the 2D6 enzyme to some degree. Care must be taken when conventional agents are co-administered with potent CYP2D6 inhibitors such as fluoxetine, paroxetine, cimetidine, erythromycin, and certain class IC antiarrhythmics (e.g., quinidine). Similarly, potent CYP3A4 inhibitors such as nefazodone, fluvoxamine, and ketoconazole should be used with care. Inhibitors of

CYP2D6 and 3A4, as well as competitive substrates, should be used carefully with conventional antipsychotics because of their potential to increase plasma levels. CYP1A2, induced by nicotine and inhibited by estrogen, plays a role in metabolizing some antipsychotics.

---

## Conclusion

---

The classic antipsychotics revolutionized the practice of psychiatry and the treatment of the severely mentally ill throughout the world. Second-generation “atypical” antipsychotics have commercially eclipsed these first-generation agents to a large extent, in that more than 90% of patients with schizophrenia and related psychoses in the United States are currently receiving one of the atypical oral agents. In regard to long-acting (depot) agents, second-generation injectable agents are gradually displacing classic antipsychotic injectables such as haloperidol decanoate and fluphenazine decanoate. The landmark National Institute of Mental Health-funded CATIE study, which compared four SGA oral agents (olanzapine, quetiapine, risperidone, and ziprasidone) against one FGA oral agent (perphenazine), showed that there was no difference between the two generations in clinical effectiveness (defined as all-cause discontinuation) ([Lieberman et al. 2005](#)). However, the CATIE study excluded subjects with tardive dyskinesia from random assignment to perphenazine and instead assigned them to one of the atypical agents. This methodological stipulation may have confounded the findings, because the 231 subjects with tardive dyskinesia were later found to have a higher severity of psychopathology and a much greater likelihood of substance use ([Nasrallah 2006](#)). Additionally, the subjects’ low propensity to develop EPS led to a “ceiling effect” finding of no EPS differences between perphenazine and the SGAs. Nonetheless, both classic antipsychotics and atypical antipsychotics can cause serious side effects, with neurological adverse events being much more likely with the FGAs and metabolic complications being more common with the SGAs.

Conventional antipsychotics will always be remembered for their critical role as the foundation of antipsychotic pharmacotherapy and as the main impetus for the remarkable neuropharmacological progress in psychiatric neuroscience over the second half of the twentieth century. They retain an important, if limited, role in the antipsychotic armamentarium of the twenty-first century.

# CHAPTER 25

## Clozapine

Stephen R. Marder, M.D.

Yvonne S. Yang, M.D., Ph.D.

---

### History and Discovery

---

Clozapine has played a critical role in the history of therapeutics for psychosis. When clozapine was initially developed in the 1960s (following its synthesis in 1958 in Switzerland), there was skepticism as to whether an agent that barely caused catalepsy in rodents could be an effective antipsychotic. According to [Hippius \(1999\)](#), there was limited enthusiasm for this drug because its profile was inconsistent with the “neuroleptic dogma” that extrapyramidal side effects (EPS) were an essential feature of an antipsychotic agent. Nevertheless, Hippius and others challenged this dogma and supported clozapine’s development in Germany. As a result, clozapine was eventually marketed in a number of countries in Europe.

Enthusiasm about clozapine's unique profile turned to despair when it was reported that 13 patients in Finland developed agranulocytosis during treatment with clozapine and that 8 of these patients died ([Griffith and Saameli 1975](#)). This news led to a near halt in research on clozapine, and in the United States, clozapine's investigational new drug application came to a standstill. However, attempts to switch patients to other antipsychotic agents resulted in substantial deterioration in some individuals ([Hippius 1999](#)). Some of these patients were switched back to clozapine and carefully monitored with regular white blood cell (WBC) counts. Thus, it was found that if clozapine was discontinued, the agranulocytosis was reversible and the drug could be readministered safely ([Honigfeld et al. 1998](#)). Moreover, studies revealed that clozapine was particularly effective for patients who were severely ill and for patients who had not responded to treatment with conventional antipsychotics ([Kane et al. 1988](#); [Kronig et al. 1995](#)). After a series of stops and starts, clozapine was finally demonstrated to have superiority over chlorpromazine for treatment-resistant schizophrenia, and it was approved by the U.S. Food and Drug Administration (FDA) in 1990 ([Crilly 2007](#); [Iqbal et al. 2003](#)).

The discovery that clozapine, the earliest second-generation antipsychotic (SGA), was an effective antipsychotic that caused minimal EPS led to a reassessment of the reigning models of the antipsychotic effect. The exact mechanism of clozapine's antipsychotic action was and remains unknown; however, its efficacy, which is greater than first-generation antipsychotics (FGAs), led to the development of the SGAs. At this point in time, attempts to comprehend clozapine's mechanism of action have produced more questions than answers in our

understanding of the physiology and pharmacology of schizophrenia; however, it remains the most effective antipsychotic.

---

## Structure-Activity Relations

---

Clozapine, or 3-chloro-6-(4-methylpiperazin-1-yl)-5H-benzo[b][1,4]benzodiazepine ([PubChem Compound Database 2016a](#)), belongs to the group of tricyclic antipsychotics known as the dibenzepines. This group is characterized by a seven-member dibenzazepine central ring substituted with oxygen, nitrogen, sulfur, or carbon ([Iskra and Decker 2012](#)). The antipsychotic dibenzepines include a loxapine-like group of compounds (the dibenzoxazepines) and a clozapine-like group (the dibenzodiazepines). The structures of clozapine and its derivatives olanzapine and quetiapine can be seen in [Figure 25-1](#). Interestingly, the structure of the FGA antipsychotic loxapine ([PubChem Compound Database 2016b](#)) is quite similar to that of clozapine, with only two substitutions distinguishing them.

---

**FIGURE 25-1.** Chemical structures of clozapine, olanzapine, quetiapine, and loxapine.

Structures of olanzapine and quetiapine are based on clozapine's chemical structure, and their similarities can be seen clearly here. It is also striking how similar the structure of loxapine, a typical antipsychotic, is to that of clozapine, the prototypical atypical antipsychotic.

*Source.* Structures from PubChem Compound Database, National Center for Biotechnology Information. Available at: <http://www.ncbi.nlm.nih.gov/pccompound>.

Clozapine is also known to be a fast-off dopamine type 2 ( $D_2$ ) receptor antagonist, with a rapid disassociation time of less than 1 minute for 50% binding of  $D_2$  receptors (Seeman 2014). Tresadern et al. (2011) examined more than 1,800 compounds and found that “increased hydrophilicity, increased number of nitrogen atoms, lower molecular weight, fewer rings, less chiral centers, and

increased partial positive charge all contribute to a faster dissociation from the D<sub>2</sub> receptor” (p. 27).

---

## Pharmacological Profile

---

To quote [Wenthur and Lindsley \(2013\)](#), “clozapine is a broad spectrum ligand,” because it binds to more receptors than perhaps any molecule in psychopharmacology ([Stahl 2013](#)). Clozapine and the other SGAs are often identified through their equal or greater antagonism of the 5-hydroxytryptamine (serotonin) type 2A (5-HT<sub>2</sub>) receptor compared with the D<sub>2</sub> receptor. However, clozapine in fact binds to more than 20 receptors more strongly than to the D<sub>2</sub> receptor and binds to at least four receptors either just as strongly or more strongly than to 5-HT<sub>2A</sub> ([Stahl 2013](#); [Wenthur and Lindsley 2013](#)). Of all the antipsychotics, quetiapine, whose structure was based on that of clozapine, is most similar in pharmacological profile to clozapine.

## Dopamine Receptors

Clozapine is a D<sub>2</sub> antagonist that binds to D<sub>2</sub> receptors approximately 50–100 times less strongly than haloperidol and 10 times less strongly than chlorpromazine ([Ashby and Wang 1996](#)). At therapeutic concentrations, clozapine occupies only 40%–60% of D<sub>2</sub> receptors, in contrast to most FGAs, which occupy more than 80% of D<sub>2</sub> receptors ([Wenthur and Lindsley 2013](#)). Clozapine binds less strongly to D<sub>2</sub> receptors than to dopamine itself and may be displaced by endogenous dopamine ([Seeman 2014](#)). It also

has equivalent occupancy of dopamine  $D_1$  and  $D_2$  receptors at therapeutic dosages ([Tauscher et al. 2004](#)). In order, clozapine binds most strongly to  $D_4 > D_1 > D_5 > D_2 > D_3$  receptors ([Wenthur and Lindsley 2013](#)).

## Serotonin Receptors

Clozapine binds to 5-HT<sub>2A</sub>, 5-HT<sub>2B</sub>, and 5-HT<sub>2C</sub> receptors 15–30 times more strongly than to  $D_2$  receptors ([Stahl 2013](#); [Wenthur and Lindsley 2013](#)). Clozapine also has high affinity for 5-HT<sub>5</sub> receptors and acts as a partial agonist at 5-HT<sub>1A</sub> receptors.

## Muscarinic Receptors

Clozapine binds strongly to muscarinic  $M_1$  receptors, and to other muscarinic receptors in the following order:  $M_1 > M_3 > M_4 > M_2$ . Clozapine's high affinity for muscarinic receptors likely causes many of clozapine's well-known side effects of sedation, constipation, and the dangerous complication of ileus.

## Adrenergic Receptors

Clozapine binds strongly to  $\alpha_1$ -adrenergic receptors in the central nervous system, based on positron emission tomography studies of <sup>3</sup>H-prazosin binding displacement in animal studies ([Ashby and Wang 1996](#)). Clozapine's antagonism of  $\alpha_1$ -adrenergic receptors likely contributes to

its sedative properties as well as some of its cardiac side effects including orthostatic hypotension and tachycardia.

## Histamine Receptors

Clozapine binds very strongly to histamine type 1 ( $H_1$ ) receptors, which likely contributes to clozapine's associated sedation, increase in appetite, weight gain, and therefore possibly diabetes and metabolic syndrome. Preliminary research has been done on histamine agonists to counteract the metabolic effects of SGAs; however, no well-powered placebo-controlled, randomized trials have been performed ([Poyurovsky et al. 2005](#)).

## Glutamate Receptors

Although clozapine does not bind directly to glutamate receptors, it has been shown to inhibit the reuptake of glycine at the synapse in rats, resulting in increased glycine at the synapse, and thus increasing *N*-methyl-D-aspartate (NMDA) receptor signaling ([Javitt et al. 2005](#)). Moreover, clozapine's main metabolite, *N*-desmethylozapine (NDMC), or norclozapine, is an  $M_1$  agonist known to increase NMDA receptor activity ([Wenthur and Lindsley 2013](#)).

## GABA Receptors

Clozapine has a low affinity for  $\gamma$ -aminobutyric acid (GABA) receptors.

## Animal Studies

Animal behavioral models have been of limited use in schizophrenia, due to a lack of well-accepted animal models of psychopathology in schizophrenia. The reasons for this are numerous. First of all, no single model has been identified that can represent the genetic complexity and breadth and variability of symptom domains of schizophrenia. Second, the subjective quality of many psychotic experiences, such as paranoia, hallucinations, and delusions, makes these symptoms and experiences difficult to measure in animals. Third, unlike the heart or the pancreas, the human brain is many times more complex than even that of a monkey, not to mention a rodent brain, for instance as evidenced by the large number of folds in the human brain and the complete absence of folds in the rodent brain. Last, *schizophrenia* and *psychosis* continue to function as “umbrella terms” for what are likely numerous diseases presenting with overlapping symptoms and syndromes, making differentiation of one illness from another difficult in humans, not to mention animal models.

Despite these limitations, a number of constructs, including prepulse inhibition and the conditioned avoidance response, are being studied from a more reductionist standpoint. These models are being looked to less as complete representations of the disease than as models of specific neurophysiological aspects of psychosis that can inform us about particular characteristics of the illness ([Wong and Josselyn 2016](#)). The use of animal models in this manner has suggested unique properties of clozapine. For instance, as reviewed by [Geyer et al. \(2001\)](#), among four techniques to induce prepulse inhibition, a sensory gating phenomenon that is thought to relate to the relative

difficulty patients with schizophrenia have separating salient from nonsalient environmental information, deficits in prepulse inhibition induced by NMDA receptor antagonists were most likely to respond to clozapine-like SGAs, and not to FGAs.

The conditioned avoidance response is another well-established construct used to predict efficacy of a potential antipsychotic agent. Conditioned avoidance response refers to learned behavior to avoid a conditioned stimulus once it has been associated with a negative unconditioned stimulus. Early on in the development of antipsychotic drugs, it was found that effective agents specifically disrupted this response, and thus exhibited dopaminergic blockade ([Wadenberg 2010](#)). Although clozapine did not meet the commonly accepted criteria of capability to cause catalepsy at higher dosages and to antagonize amphetamine-induced stereotypies in animals, it does block the conditioned avoidance response, suggesting that it has antipsychotic efficacy.

---

## Pharmacokinetics and Disposition

---

Clozapine is readily absorbed orally. However, because of extensive first-pass metabolism, its absolute oral bioavailability is only moderate. Peak plasma levels of clozapine are reached approximately 2 hours after oral administration. The elimination half-life is about 12 hours, and patients will usually reach steady-state plasma concentrations within 7 days. The coadministration of highly protein-bound drugs may lead to increased free

clozapine levels, although the total (free plus bound) levels may be unchanged. Clozapine's volume of distribution is lower than that of other antipsychotic drugs but is nonetheless large, with a mean of 2.0–5.1 L/kg (range: 1.0–10.2 L/kg). Clozapine crosses the blood–brain barrier easily.

As mentioned, clozapine undergoes extensive first-pass metabolism in the liver and gut. Although clozapine is predominately metabolized by cytochrome P450 (CYP) 1A2, CYP2D6 and CYP3A3/4 also contribute ([Buur-Rasmussen and Brøsen 1999](#); [Wenthur and Lindsley 2013](#)).

Plasma concentrations of clozapine average about 10–80 ng/mL per mg of drug given per kg of weight. Thus, a typical daily dose of 300–400 mg (about 5 mg/kg) is associated with plasma levels ranging between 200 ng/mL and 400 ng/mL. However, there is considerable variability among individuals treated with clozapine. A number of studies have focused on the clinical implications of this variation in plasma concentrations. These studies, when taken together, indicate that patients are more likely to do well when their plasma levels are greater than 350 ng/mL ([Bell et al. 1998](#); [Kronig et al. 1995](#); [Miller 1996](#); [Miller et al. 1994](#); [Potkin et al. 1994](#)). If patients have not responded after 6 weeks with a plasma level of 250 ng/mL, the clinician should increase the level to approximately 350 ng/mL. High levels, such as 600 ng/mL, are not associated with a greater likelihood of improvement than are moderate levels, and they may be associated with a higher incidence of side effects. Therefore, patients with high levels and side effects may benefit from having the dosage reduced. In interpreting plasma concentrations of clozapine, it is important for clinicians to consider whether the laboratory is reporting just the parent drug or

clozapine plus norclozapine. If it is the combination, levels will be higher.

---

## Pharmacogenetic Profile

---

In recent years, a number of studies have been done linking genetic polymorphisms to either response to clozapine or likelihood of side effects such as weight gain and agranulocytosis in patients. Specific genetic polymorphisms include the D<sub>3</sub> receptor gene *rs6280*, where substitution of glycine for serine in a coding region of the genes is associated with higher response rates to clozapine and risperidone ([Moore et al. 2014](#)). Polymorphisms of the HLAQB1 gene, an allele at the major histocompatibility complex, are associated with greater likelihood of developing agranulocytosis, especially during rechallenge with clozapine after a prior episode of agranulocytosis. CYP genetic variants have been associated with decreased response to clozapine, and polymorphisms in the gene for brain-derived neurotrophic factor (BDNF) have been found to be associated with improved response ([Srirenakumar et al. 2015](#)). The Pro12Ala polymorphism of the PPAR- $\gamma$ 2 gene appears to predispose patients on clozapine to metabolic syndrome: patients with the Pro-Ala substitution had a 53.8% likelihood of having metabolic syndrome, whereas Pro-Pro polymorphism patients had only a 16.3% likelihood ([Fernández et al. 2012](#)). Although not yet integrated into clinical practice, the pharmacogenetics of clozapine may soon help to inform clinicians about the likelihood of a patient to either respond to clozapine treatment or to develop a concerning side effect.

---

# Mechanism of Action

---

The effectiveness of antipsychotics was previously thought to be associated with dopamine D<sub>2</sub> receptor blockade, and induction of EPS was thought to be necessary for antipsychotic action. Clozapine's low rates of EPS but superior efficacy as an antipsychotic undermined and eventually overturned these ideas. Currently, the exact mechanism of clozapine's antipsychotic effect remains unknown, but several theories have been proposed. In this section, we will discuss the possible mechanisms of both clozapine's low rate of EPS as well as its highly effective antipsychotic effect.

## Mechanisms of Clozapine's Low Propensity to Cause EPS

### Dual 5-HT<sub>2A</sub>-D<sub>2</sub> Antagonism

It has been thought that the low level of EPS from clozapine treatment (and many other SGAs) was due to its greater activity at the 5-HT<sub>2A</sub> receptor than at the D<sub>2</sub> receptor ([Meltzer and Massey 2011](#); [Meltzer et al. 1989, 2003](#)). This model, as laid out by [Stahl \(2013\)](#), is as follows: D<sub>2</sub> receptor antagonism in the mesolimbic pathway (projecting from the midbrain ventral tegmental area to the nucleus accumbens) reduces excessive dopamine signaling in the nucleus accumbens and reduces positive symptoms. However, D<sub>2</sub> receptor antagonism of the nigrostriatal pathway, which projects from the substantia nigra to the striatum of the basal ganglia, causes Parkinson-like involuntary

movements, dystonias, and other EPS. Clozapine's antagonism of the 5-HT<sub>2A</sub> receptor in the striatum results in increased local release of D<sub>2</sub>, which results in relief from the EPS caused by D<sub>2</sub> antagonism. Similarly, in the tuberoinfundibular tract, which projects from the hypothalamus to the anterior pituitary gland, D<sub>2</sub> antagonism causes increased prolactin secretion, resulting in gynecomastia, galactorrhea, amenorrhea, and decreased libido. Local 5-HT<sub>2A</sub> antagonism at the pituitary gland from SGAs increases local D<sub>2</sub> signaling and thus reverses the increase in prolactin secretion.

Although this characteristic of the SGAs may be associated with their relatively lower rates of EPS compared with FGAs, there is evidence that calls this into question. For instance, risperidone has high affinity for 5-HT<sub>2A</sub> receptors yet also has high rates of gynecomastia and galactorrhea. Also, quetiapine produces very few EPS but has no specificity for 5-HT<sub>2A</sub> receptors.

### **Low Percentage of D<sub>2</sub> Receptor Occupancy**

Clozapine and some other SGAs have been shown to occupy less than 60% of D<sub>2</sub> receptors at therapeutic doses, in contrast to the greater than 80% D<sub>2</sub> receptor binding of agents in the FGA class. This may explain the low rate of EPS with most SGAs.

### **Fast-Off D<sub>2</sub> Receptor Dissociation**

It has been proposed by [Kapur and Seeman \(2001\)](#) and others that it is the rapid dissociation of clozapine from the D<sub>2</sub> receptor that could give rise to its low occurrence of EPS and efficacy for psychosis. This fast dissociation, or

“loose binding,” characteristic allows clozapine to be displaced by endogenous dopamine, thus allowing more physiological signaling than during treatment with most other antipsychotics. In their 2001 review, Kapur and Seeman noted that if D<sub>2</sub> receptor occupancy was high, EPS occurred even in the presence of strong 5-HT<sub>2A</sub> antagonism, whereas rapid dissociation from the D<sub>2</sub> receptor in in vitro studies had the closest correlation with atypicality.

## Mechanisms of Clozapine's Exceptional Antipsychotic Efficacy

To date, clozapine remains the most effective antipsychotic in the clinician's arsenal. What could explain clozapine's superior efficacy? Let us examine two very similar antipsychotics, clozapine and its derivative quetiapine. Clozapine and quetiapine have very similar pharmacological profiles, have the highest dissociation constants from the D<sub>2</sub> receptor, have fast-off dynamics at the D<sub>2</sub> receptor, and have high binding affinity to the 5-HT<sub>2A</sub> receptor. However, the antipsychotic efficacy of quetiapine cannot match that of clozapine ([McEvoy et al. 2006](#)). What can explain clozapine's superior efficacy over all other antipsychotics? This remains one of the ongoing mysteries in the treatment of schizophrenia. A few theories are discussed in the next four subsections.

### **D<sub>1</sub>:D<sub>2</sub> Equivalent Occupancy**

The differences in efficacy between clozapine and quetiapine despite their similarities could be explained by

the differential D<sub>1</sub>:D<sub>2</sub> occupancy ratio between clozapine and the other members of the SGA class. In a positron emission tomography study using <sup>11</sup>C-SCH23390 and <sup>11</sup>C-raclopride to determine D<sub>1</sub> and D<sub>2</sub> receptor occupancy in patients with schizophrenia, clozapine was found to have the highest D<sub>1</sub>:D<sub>2</sub> receptor occupancy ratio (0.88), compared with olanzapine (0.54), quetiapine (0.41), and risperidone (0.31) ([Tauscher et al. 2004](#)).

### **D<sub>4</sub> Receptor Binding**

Clozapine also has a very high affinity for the dopamine 4 (D<sub>4</sub>) receptor. The D<sub>4</sub> receptor is widely distributed in the cortex and less so in striatal areas. Because of clozapine's specific high binding to D<sub>4</sub> receptors, it was thought this D<sub>4</sub> binding could be the unique characteristic giving clozapine its superior efficacy against psychosis. However, other agents with high D<sub>4</sub> receptor activity have failed to demonstrate antipsychotic activity.

### **Combination of Activity at Multiple Specific Receptor Types**

Of the theories just discussed, none individually can explain the unique efficacy of clozapine for psychosis. Another possibility is that the unique signature of clozapine's receptor binding profile among the dopaminergic, serotonergic, adrenergic, histaminergic, and muscarinic receptors explains its unique efficacy. It is also possible that clozapine has unknown activity at other receptors such as glutamate, GABA, and neuropeptides receptors.

### **Metabolites**

It has been thought that clozapine's primary metabolite, NDMC, or norclozapine, may have a role in its antipsychotic effect, because it represents 10%–90% of circulating active drug in patient serum ([Wenthur and Lindsley 2013](#)). However, trials of norclozapine have not demonstrated antipsychotic efficacy.

---

## Indications and Efficacy

---

### Acute Schizophrenia and Schizoaffective Disorder

Because of its side-effect profile, clozapine should not be administered as a first-line agent for schizophrenia or schizoaffective disorder. However, it should be considered a second- or third-line agent. In a recent meta-analysis of 15 antipsychotics that included 43,049 patients and considered often-used antipsychotics including olanzapine, risperidone, haloperidol, quetiapine, and aripiprazole, clozapine was found to be the most effective antipsychotic based on change in symptoms ([Leucht et al. 2013](#)).

### Treatment-Refractory Schizophrenia

Early studies suggested that clozapine was particularly effective in patients with more severe treatment-refractory forms of schizophrenia. This was important when it was discovered that clozapine was associated with a risk of agranulocytosis. Given that clozapine was viewed as an agent that might be helpful for patients who had not

responded to other antipsychotics, a study was designed to test whether there was a role for clozapine in this population. The result was the design of a multicenter study comparing clozapine with chlorpromazine in severely ill patients with treatment-refractory schizophrenia ([Kane et al. 1988](#)). Treatment-refractory illness was characterized on the basis of a history of drug nonresponsiveness and a lack of improvement during a 6-week trial of up to 60 mg of haloperidol. Treatment with clozapine resulted in greater improvement in nearly every dimension of psychopathology. Thirty percent of the clozapine-treated patients met stringent improvement criteria, compared with only 4% of those treated with chlorpromazine.

Other studies suggest that the proportion of patients improving with clozapine treatment will be higher if clozapine is continued for a longer time. For example, a 16-week trial by [Pickar et al. \(1992\)](#) found a 38% improvement rate. A more recent report ([Kane et al. 2001](#)) found that 60% of patients with treatment-refractory illness improved after a 29-week trial of clozapine.

Two large trials compared clozapine with SGAs in patients with treatment-resistant illness. In the United States, the National Institute of Mental Health Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) compared clozapine with risperidone, olanzapine, or quetiapine in patients with schizophrenia who had not shown a positive response in an earlier phase of the study because of a lack of efficacy ([Stroup et al. 2006](#)). Clozapine was administered open-label, whereas the other antipsychotics were administered double-blind. Patients assigned to clozapine had the lowest discontinuation rates, with 56% of patients taking clozapine discontinuing treatment, compared with 71% of those taking olanzapine,

86% of those taking risperidone, and 93% of those taking quetiapine. Clozapine-treated patients also showed greater symptom improvement than those receiving the other agents. Another trial in the United Kingdom, the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study—band 2 (CUtLASS-2) ([Lewis et al. 2006](#)), randomly assigned 136 patients who had responded poorly to two prior antipsychotics to either clozapine or an SGA selected prior to the randomization. Patients who received clozapine demonstrated greater improvement than those taking the comparison drugs.

A large body of evidence indicates that clozapine has an important role in the treatment of patients who have not responded to either FGAs or other SGAs. Clozapine's advantages are clearest in patients who have not responded to FGAs, but they are still apparent in those who have had an inadequate response to other SGAs. Because clozapine is associated with a risk of agranulocytosis and other side effects (summarized in this chapter in the section "Side Effects and Toxicology"), patients should probably receive a trial of one or two other SGAs before receiving a trial of clozapine. Clinical guidelines ([Lehman et al. 2004a, 2004b](#); [Marder et al. 2002](#); [Miller et al. 2004](#)) differ to a minor degree on the number of trials that should precede a trial with clozapine, but most recommend at least two agents, one of which is an SGA. There is a consensus that patients should not be considered to have treatment-refractory illness until they have received an adequate treatment trial with clozapine.

# Hostile and Aggressive Behavior in Schizophrenia

Clozapine may have other advantages for patients with schizophrenia. A number of studies suggest that clozapine may decrease hostility and aggression, compared with other agents. In a study of 157 inpatients ([Citrome et al. 2001](#)), clozapine resulted in greater reductions in the hostility item from the Positive and Negative Syndrome Scale (PANSS) than did the FGAs and other SGAs. A study by [Chengappa et al. \(2003\)](#) found significant reductions in the rates of seclusion and restraint among patients with schizophrenia who received clozapine during the first 3 years after its introduction. Other randomized studies have consistently found that patients treated with clozapine exhibit less hostility and less aggressive behavior than patients taking comparators ([Essock et al. 2000](#); [Kane et al. 1988](#)). In an observational prospective study of outpatients, the Intercontinental Schizophrenia Outpatient Health Outcomes (IC-SOHO) study, however, clozapine was not found to be superior to olanzapine, quetiapine, or risperidone monotherapy for reduction of hostile and aggressive behavior ([Bitter et al. 2005](#)). These findings suggest that clozapine may be of particular benefit to patients with treatment-refractory illness who demonstrate hostile and aggressive behavior, especially while on inpatient units.

## Schizophrenia Patients With High Suicide Risk

Clozapine may also be a preferred agent for patients with schizophrenia who are at a higher risk for suicide. Large epidemiological studies have found that mortality from suicide is reduced among individuals taking clozapine ([Reid et al. 1998](#); [Walker et al. 1997](#)). [Meltzer and Okayli \(1995\)](#) followed patients who were switched to clozapine and found a reduction in the number of serious suicide attempts as well as in expressed depression and hopelessness. One convincing study was a comparison of clozapine and olanzapine in 980 patients with schizophrenia who were considered at risk for suicide. In that study, clozapine was more effective in reducing the risk of suicide ([Meltzer 2002](#)). In a more recent Finnish study, SGAs were associated with decreased mortality in first-episode patients, whereas FGAs were associated with increased mortality. When clozapine, olanzapine, quetiapine, and risperidone were compared, only clozapine was found to have a strong antisuicide effect ([Kiviniemi et al. 2013](#)).

## Schizophrenia With Comorbid Substance Abuse

Although the effectiveness of clozapine in patients with comorbid substance abuse has not been demonstrated in randomized controlled trials, there is some supporting evidence from naturalistic studies. One retrospective study ([Green et al. 2003](#)) found that patients treated with clozapine were more likely than those treated with risperidone to abstain from alcohol and cannabis use. A prospective study ([Green et al. 2007](#)) found that patients treated with clozapine were often able to reduce their substance abuse. This finding was supported by other

prospective studies ([Brunette et al. 2006](#); [Drake et al. 2000](#)), indicating that clozapine is effective for reducing substance abuse.

## Mania in Bipolar Disorder

Given that all available antipsychotics are effective in reducing manic symptoms, it is not surprising that clozapine is effective for bipolar mania. However, accumulating evidence suggests that clozapine is particularly effective for manic symptoms that are not responsive to other agents. [McElroy et al. \(1991\)](#) were among the first to observe clozapine's unique effects in patients with bipolar disorder. Subsequent studies have confirmed clozapine's effectiveness as monotherapy and as a supplementation medication for mania in bipolar disorder. In an open-label randomized trial in acutely manic patients ([Barbini et al. 1997](#)), clozapine was as effective as chlorpromazine and had a more rapid onset of action. [Suppes et al. \(1999\)](#) randomly assigned patients with treatment-resistant schizoaffective or bipolar illness to either supplemental clozapine or treatment as usual during a 1-year open-label trial. Among both groups of patients, those treated with clozapine demonstrated greater improvement.

## Treatment-Resistant and Rapid-Cycling Bipolar Disorder

In addition to efficacy for mania, treatment-resistant schizophrenia, and treatment-resistant schizoaffective

disorder, there is evidence that clozapine is effective for treatment-resistant bipolar disorder as well. Interest was initially sparked when several case series demonstrated that clozapine reduced the number of inpatient hospitalizations, polypharmacy, and frequency of cycling in both psychotic and nonpsychotic treatment-resistant bipolar disorder, as well as rapid-cycling bipolar disorder ([Calabrese et al. 1991](#); [Frye et al. 1996](#); [Suppes et al. 1994](#)). Several open-label studies went on to demonstrate similar results: clozapine was effective and well tolerated in patients with treatment-resistant bipolar disorder ([Calabrese et al. 1996](#); [Ciapparelli et al. 2000](#); [Green et al. 2000](#)), although [Suppes et al. \(2004\)](#) later showed that patients with rapid-cycling treatment-resistant bipolar disorder were less responsive to clozapine than non-rapid-cycling patients. Psychotic bipolar disorder was not found to be more predictive of response than nonpsychotic bipolar disorder ([Gitlin 2006](#)). More recently, a 2-year retrospective study of 21,473 patients, of whom 326 were taking clozapine, found a decreased number of inpatient days and total psychotropic medication burden for those treated with clozapine ([Nielsen et al. 2012](#)). The only randomized, treatment-as-usual controlled study ([Suppes et al. 1999](#)) showed fewer hospitalizations and decreased polypharmacy for patients randomly assigned to receive clozapine compared with treatment as usual. The striking dearth of large-scale, randomized, double-blind studies for use of clozapine in bipolar disorder can be explained by clozapine's risk of dangerous effects including cardiomyopathy, seizures, and agranulocytosis; its compliance burden due to side-effect profile and regular blood draws; and absence of patent protection ([Gitlin 2006](#)).

# Depression With Psychotic Features

Limited evidence suggests that clozapine is effective as monotherapy and as an adjunctive treatment for patients with major depression with psychotic features. This evidence is currently confined to case reports with relatively small numbers of cases ([Ranjan and Meltzer 1996](#); [Rothschild 1996](#)).

# Psychosis in Parkinson's Disease

Psychosis with delusions and hallucinations occurs in approximately 25% of patients with Parkinson's disease ([Wolters and Berendse 2001](#)). These symptoms frequently appear in patients who are receiving dopaminomimetic drugs, but they may also occur as a result of a cholinergic deficit. Three double-blind studies ([The French Clozapine Parkinson Study Group 1999](#); [Jones and Stoukides 1992](#); [The Parkinson Study Group 1999](#); [Pollak et al. 2004](#)) found that clozapine at doses as low as 25–50 mg was effective in reducing psychotic symptoms. Moreover, these doses were not associated with an increase in tremor and rigidity. A report from the American Academy of Neurology ([Miyasaki et al. 2006](#)) recommended clozapine as a preferred agent for psychosis in Parkinson's disease.

# Schizophrenia in Children and Adolescents

Two randomized controlled trials from the National Institute of Mental Health have evaluated the effectiveness

of clozapine in childhood-onset schizophrenia. The first ([Kumra et al. 1996](#)) compared clozapine and haloperidol in individuals with a mean age of about 14 years who had done poorly on FGAs. Clozapine was superior for both positive and negative symptoms. A more recent double-blind study ([Shaw et al. 2006](#)) compared clozapine and olanzapine in subjects with a mean age of about 12 years. The results from this study were less clear. Although there were substantial differences favoring clozapine, the differences were statistically significant only for negative symptoms. The small sample ( $n=12$  for clozapine and  $n=13$  for olanzapine) was a limiting factor for obtaining statistical significance. Both studies found that this younger population appeared to be particularly vulnerable to clozapine's side effects. Nevertheless, these studies suggest an important role for clozapine in younger patients with schizophrenia with refractory symptoms.

## Augmentation Strategies in Partial Responders to Clozapine

A number of studies have evaluated augmentation strategies for individuals who are partial responders to clozapine. A recent meta-analysis ([Sommer et al. 2012](#)) reviewed 29 double-blind randomized trials of agents used to augment the effects of clozapine. The most-studied antipsychotics added to clozapine were risperidone and aripiprazole, and the most-studied mood stabilizer was lamotrigine. Although some of the studies reported positive findings, none of the strategies was viewed as having adequate empirical support. Augmentation with electroconvulsive therapy has been shown to be more

promising, with a recent prospective, randomized study demonstrating a 50% response rate in patients treated with clozapine who received electroconvulsive therapy compared with those who received only clozapine ([Petrides et al. 2015](#)).

## Maintenance Therapy in Schizophrenia

Clozapine use has largely been confined to patients with treatment-refractory schizophrenia. As a result, clozapine has not been studied in traditional relapse prevention designs in which patients who are stable are randomly assigned to either clozapine or a comparator. Nevertheless, there are substantial data supporting clozapine's long-term effectiveness. [Breier et al. \(2000\)](#) evaluated the outcomes of 30 patients with schizophrenia who received clozapine for 1 year. Patients taking clozapine experienced fewer relapses and rehospitalizations than they did in the year prior to being changed to clozapine. A study in the state hospitals in Connecticut compared patients who were assigned to clozapine with patients who were maintained on their usual antipsychotics ([Essock et al. 2000](#)). Although clozapine did not result in a greater likelihood of hospital discharge, patients who were treated with clozapine had a higher likelihood of remaining in the community following discharge. This finding supports the observation that clozapine is associated with a reduced risk of relapse compared with conventional antipsychotics.

A study from the U.S. Department of Veterans Affairs Cooperative Studies Program compared haloperidol and clozapine in patients with treatment-refractory

schizophrenia ([Rosenheck et al. 1997](#)). This study was not designed as a relapse prevention trial but rather as a comparison of the two agents in individuals who were poor responders to conventional therapy. However, the 1-year study is somewhat informative about the usefulness of the two drugs in patients living in the community. Fifty-seven percent of the patients taking clozapine completed the study, compared with only 28% of the patients taking haloperidol ( $P<0.001$ ). Using 20% improvement on the PANSS as the criterion for response, the investigators found that 42% of patients treated with clozapine and 31% of patients treated with haloperidol were responders ( $P=0.09$ ). In addition, clozapine-treated patients had fewer mean days of hospitalization (143.8 days) compared with haloperidol-treated patients (168.1 days;  $P=0.03$ ).

## Other Indications

Clozapine may also help patients with polydipsia-hyponatremia syndrome ([Canuso and Goldman 1999](#)). Patients with this syndrome tend to intoxicate themselves through excessive water drinking, and the resultant hyponatremia may result in seizures.

Clozapine has historically been used to treat tardive dyskinesia (TD), although it has not been formally studied extensively for this purpose. In a 1991 review, Lieberman et al. reviewed eight small studies and conducted their own study of 30 patients with TD and found that in 50% of patients with TD, clozapine reduced their TD symptoms by approximately 43% ([Lieberman et al. 1991](#)). Other studies found equivocal results; however, in no study did clozapine cause TD to worsen. [Kimiagar et al. \(2012\)](#) found TD

symptoms were reversed with a combination of clozapine, clonazepam, and tetrabenazine. Clozapine's mechanism of action in reducing TD remains unknown.

---

## Side Effects and Toxicology

---

### Hematological Effects

The side effects of clozapine make it one of the most challenging medications for psychiatrists to prescribe. The main factor that limits its use is the potential serious side effect of agranulocytosis. Agranulocytosis is defined as a drop in absolute neutrophil count (ANC) to levels below 500/mm<sup>3</sup>. In 1975, there were 17 cases of agranulocytosis in Finland, and widespread use of the medication for the treatment of schizophrenia was temporarily halted ([Amsler et al. 1977](#); [de la Chapelle et al. 1977](#)).

Agranulocytosis is a potentially lethal side effect that occurs in less than 1% of patients treated in the United States ([Alvir et al. 1993](#)). In the United States, all patients who are taking clozapine are entered into a national registry known as the Clozapine Risk Evaluation and Mitigation Strategy (REMS) Program ([www.clozapinerems.com](http://www.clozapinerems.com)). Through this national registry, patients are prescribed the medication only if their ANC count shows no signs of clinically meaningful suppression ([Honigfeld 1996](#)). In a review of the morbidity and mortality of clozapine-treated patients ([Honigfeld et al. 1998](#)) over a 5-year period, 99,502 patients were registered through the previous Clozaril National Registry. Of these, 2,931 (2.95%) patients developed leukopenia (WBC count=3,500/mm<sup>3</sup>),

and 382 (0.38%) patients developed agranulocytosis (ANC  $<500/\text{mm}^3$ ). Twelve of the cases of agranulocytosis (0.012%) were fatal.

When clozapine treatment is discontinued upon identification of marked leukopenia, patients usually recover within 14-24 days and without any long-term consequences. However, rechallenging patients who have experienced agranulocytosis almost always leads to recurrence of the problem. The onset of the second episode is more aggressive than that of the first. In nine patients who were known to be rechallenged, the average time to onset of the second episode was 10 weeks shorter (14 weeks) than for the first episode (24 weeks) ([Safferman et al. 1992](#)). Agranulocytosis has been successfully treated by discontinuing the medication, providing supportive measures, and administering granulocyte colony-stimulating factor, a medication that is commonly prescribed to patients with medical illnesses that precipitate WBC count suppression ([Raison et al. 1994](#); [Weide et al. 1992](#); [Wickramanayake et al. 1995](#)).

In January 2006, Novartis and the FDA issued a notification to clinicians regarding modifications to the recommended monitoring schedule for patients receiving clozapine. In October 2015, these guidelines were updated under a unifying national registry, the Clozapine REMS Program. In order to prescribe clozapine, the prescribing physician, the dispensing pharmacy, and the patient must be registered with the REMS Program. Under the new monitoring guidelines, a patient beginning clozapine treatment must have a baseline ANC count of no less than  $1,500/\text{mm}^3$ , or  $1,000/\text{mm}^3$  if the patient has benign ethnic neutropenia. If during clozapine treatment a patient's ANC drops below  $1,000/\text{mm}^3$ , clozapine must be stopped; for

patients with benign ethnic neutropenia, treatment must be stopped if the ANC drops below 500/mm<sup>3</sup>. Weekly ANC levels must be obtained for 6 months, at which time the frequency can be reduced to every 2 weeks, provided that treatment and monitoring have not been interrupted and WBC counts and ANCs have remained within acceptable ranges. After 1 year, monitoring can be reduced to monthly blood tests.

## Cardiac Effects

Well-known side effects of clozapine on the cardiovascular system include tachycardia, bradycardia, syncope, and orthostatic hypotension. Tachycardia is thought to be attributable to the anticholinergic activity of the medication at the M<sub>2</sub> receptor, leading to vagal nerve inhibition, hypotension is due to  $\alpha$ -adrenergic blockade, and bradycardia is thought to be neurally mediated reflex bradycardia, also known as the vasovagal response. The forms of cardiovascular toxicity that are of greatest concern, however, are clozapine-associated myocarditis and cardiomyopathy. In January 2002, Novartis reported that there had been 213 cases of myocarditis, 85% of which occurred at recommended dosages of clozapine within the first 2 months of therapy ([Novartis 2002](#)). The presence of eosinophilia in many of the reported cases indicates that an immunoglobulin E (IgE)-mediated hypersensitivity reaction may be involved ([Kilian et al. 1999](#)). [Novartis \(2002\)](#) also reported 178 cases of clozapine-associated cardiomyopathy, 80% of which were in patients younger than 50 years. Almost 20% of the incidents resulted in death, an alarming figure that may reflect delay in diagnosis and treatment. A

later review spanning the years 1970 through 2004, however, indicated that overall the rate of potentially fatal cardiomyopathy or myocarditis was between 0.015% and 0.188%, low enough to justify continued treatment with clozapine ([Merrill et al. 2005](#)).

The detection of cardiac toxicity is challenging, because its manifestations (tachycardia, fatigue, and orthostatic hypotension) are frequently observed in clozapine-treated patients, particularly when alterations in dosage are made ([Lieberman and Safferman 1992](#)). [Alawami et al. \(2014\)](#) found in a 2014 review that cardiac toxicity in the form of cardiomyopathy occurred, on average, 14.4 months after initiation of treatment, indicating this potentially life-threatening condition could occur long after the greatest threat of other side effects such as agranulocytosis has passed. The poor specificity of signs for cardiac toxicity demands that patients with any personal or family history of heart disease be identified, and the threshold for medical evaluation of patients developing respiratory and cardiovascular symptoms must be low ([Wooltorton 2002](#)). Therefore, we recommend monitoring of erythrocyte sedimentation rate and/or C-reactive protein, eosinophil count, and troponins on a weekly basis for the first 4 weeks of therapy ([Freudenreich and McEvoy 2016](#)). The etiology of the myocarditis and cardiomyopathy remains unclear at this time.

For hypotension caused by clozapine, we also recommend a slow upward titration of the medication and monitoring of orthostatic vital signs during the first weeks of therapy. Patients should be educated about the risk of orthostatic hypotension and should be taught to rise slowly from supine positions. Concomitant treatment with  $\beta$ -blocking agents may be necessary for persistent tachycardia. However, the

use of  $\beta$ -blockers may exacerbate the hypotensive effects of clozapine and should be used cautiously.

## Metabolic Effects

### Weight Gain

Weight gain has been observed in both premarketing and postmarketing trials of clozapine ([Henderson 2001](#); [Simpson and Varga 1974](#); [Wirshing et al. 1998, 1999](#)). [Allison et al. \(1999\)](#) performed a meta-analysis of the weight-gain data in short-term trials of medications. The average weight gain observed with clozapine was 4.45 kg, which exceeded the weight gain observed with all of the other medications in the study, including the conventional agent thioridazine (3.19 kg), a medication known for its weight-gain liability. The weight gain observed with clozapine seems to occur for a prolonged period of time—up to 40 weeks. In one naturalistic study, [Henderson \(2001\)](#) observed patients in a clozapine clinic for 5 years and noted weight gain occurring for up to 46 months in some patients.

Phase II of CATIE provided an opportunity to compare weight gain among patients assigned to clozapine, olanzapine, risperidone, and quetiapine ([McEvoy et al. 2006](#)). The numbers of patients assessed in the analyses were small, with only 45 patients in the clozapine group, 17 in the olanzapine group, 14 in the quetiapine group, and 14 in the risperidone group. Although the differences in weight gain among these agents were not statistically significant, they were interesting, with patients taking clozapine gaining a mean of 0.5 lb per month, compared with 1.0 lb with olanzapine, 0.4 lb with quetiapine, and 0.5 lb with risperidone.

## Diabetes

The weight gain observed with clozapine can place patients at risk for significant health problems. Diabetes is naturally the most concerning potential sequela of this weight gain. Numerous case reports have linked clozapine with new-onset diabetes ([Wirshing et al. 1998](#)). In [Henderson's \(2001\)](#) naturalistic study of 81 patients observed over a 5-year period, 36.6% of the patients developed diabetes.

Patients treated with clozapine should be routinely screened for diabetes and other metabolic abnormalities, including raised lipid levels. Patients with risk factors for diabetes should be monitored more closely. Reports and clinical experience suggest that in a case of antipsychotic-associated diabetes or diabetic ketoacidosis, discontinuation of the antipsychotic agent may result in reversal of the hyperglycemia and diabetes. During clozapine therapy, we recommend monitoring fasting glucose, cholesterol, and lipids at baseline and every 6 months thereafter.

Prevention of weight gain with clozapine, through nutrition and diet counseling, is recommended. Caloric restriction and exercise for 30 minutes per day should be recommended. Screening questions by physicians that we find useful include the following: "Have you noticed if your belt or pants size has changed?" "Have you noticed an increase in thirst or urinary frequency?"

## Dyslipidemias

Clozapine treatment is associated with dyslipidemias, including elevations in triglycerides and cholesterol, particularly low-density lipoprotein cholesterol ([McEvoy et al. 2006](#); [Wirshing et al. 2002a](#)).

In 2004, in response to growing concern that the majority of antipsychotic medications may be associated with weight gain and other metabolic changes, the American Diabetes Association and other groups published a set of guidelines for monitoring weight, glucose, and lipids ([American Diabetes Association et al. 2004](#)). Also in 2004, a very comprehensive literature review was conducted by [Marder et al. \(2004\)](#) to provide guidance to clinicians regarding monitoring of weight, glucose, lipids, and other parameters of physical health in patients with schizophrenia. Labeling changes were made for all antipsychotic medications, including clozapine, regarding these metabolic risk factors.

## Seizures

A well-known side effect of clozapine treatment is the risk for seizures, which are thought to occur in 5%-10% of patients treated with this medication ([Welch et al. 1994](#)). The cause of seizures is unclear, but it is generally thought that rapid escalations in dosage and possibly high plasma levels of clozapine may account for the development of seizures ([Klimke and Klieser 1995](#)). Clozapine-associated seizures occur most often at dosages greater than 600 mg/day. The relationship between clozapine plasma levels and seizures is somewhat inconsistent in the literature ([Simpson and Cooper 1978](#); [Vailleau et al. 1996](#)).

The anticonvulsant agents sodium valproate, gabapentin, and topiramate have been used successfully to treat clozapine-induced seizures ([Navarro et al. 2001](#); [Toth and Frankenburg 1994](#); [Usiskin et al. 2000](#)). Topiramate has an advantage over sodium valproate in that it is associated with very little weight gain. In cases in our clinic where

patients have developed seizures while taking clozapine, we institute rapid loading with anticonvulsant medication and temporarily discontinue the clozapine treatment. We then slowly reintroduce and retitrate the clozapine once the patient is taking an adequate dose of anticonvulsant medication.

## Anticholinergic Effects

Anticholinergic side effects resulting from clozapine's muscarinic receptor antagonism include sedation, weight gain, dry mouth, constipation, and, in some cases, ileus and/or bowel obstruction. Constipation can be a difficult but important side effect to manage in severely mentally ill individuals, who may not complain about the problem until a medical emergency, such as acute bowel obstruction, occurs. In institutional settings and in prisons, where patients may have little access to exercise and where monitoring of patients' fluid intake is not performed, constipation from clozapine can be serious or even fatal ([Drew and Herdson 1997](#); [Hayes and Gibler 1995](#); [Levin et al. 2002](#)). Typically, constipation can be avoided by proactive modifications in patients' diets and education about adequate fluid intake and exercise. The medical treatment that we favor is prophylactic therapy with sorbitol. We are less inclined to recommend treatments involving bulking agents, particularly in the setting of poor fluid intake. High-fiber diets can also be beneficial.

## Other Side Effects

Sedation is one of the most common and difficult side effects of clozapine to manage. Patients with sedation often do not want their dosages increased and will complain of sedation as one of the most annoying consequences of clozapine treatment ([Angermeyer et al. 2001](#)). In our experience, sedation is usually the limiting factor controlling both the rate at which the dose of clozapine can be increased and the maximum dosage the patient can tolerate. However, no rigorous studies have been published.

There have been several reports of respiratory arrest or depression during the early stages of treatment with clozapine ([Novartis 2002](#)). Two of the patients who experienced respiratory arrest were concomitantly taking benzodiazepines.

Sialorrhea is a commonly reported side effect of clozapine (occurring in over 50% of patients) that can be problematic for patients. The etiology of sialorrhea is unclear, but the condition does not seem to be caused by the dopamine blockade. It may be mediated through  $\alpha$ -adrenergic receptor blockade. Case series and small pilot studies indicate that treating sialorrhea with antiadrenergic agents, such as the clonidine patch, or anticholinergic agents, such as benztropine and intranasal ipratropium bromide, or atropine ophthalmic drops administered sublingually, may be successful ([Calderon et al. 2000](#)). We generally recommend that patients sleep with a towel on their pillow, as this side effect seems to be most bothersome during the night. Unfortunately, the use of concomitant antiadrenergic or anticholinergic agents adds to the potential side-effect burdens of hypotension and constipation, respectively.

Neuroleptic malignant syndrome, a syndrome of unknown etiology that includes hyperthermia, autonomic instability,

and severe rigidity, has been reported in several patients treated with clozapine ([Anderson and Powers 1991](#)). The etiology of neuroleptic malignant syndrome that occurs in the context of clozapine use, as well as that occurring with use of conventional antipsychotics, remains unclear.

Hepatotoxicity has been reported with clozapine, especially in the setting of polypharmacy ([Macfarlane et al. 1997](#); [Wirshing et al. 1997](#)). Asymptomatic elevation of transaminase levels was observed most commonly, affecting between 30% and 50% of patients treated with clozapine. Icteric hepatitis was uncommonly seen in [Macfarlane et al.'s \(1997\)](#) review of clozapine-related hepatotoxicity and was noted in 84 of 136,000 patients (0.06%). Fatal acute fulminant hepatitis has been documented in 2 patients (0.001%). Although serious toxicity is rare, prescribers of clozapine should be aware of its hepatotoxic potential.

Sexual side effects, including priapism and impotence, have been reported with clozapine. Urinary retention and bladder dysfunction can also result from treatment with clozapine. In a study surveying patients' sexual side effects, we found that clozapine-treated patients actually had fewer sexual complaints than patients on other antipsychotic medications (e.g., fluphenazine, risperidone) ([Wirshing et al. 2002b](#)).

Clozapine has been shown to induce de novo obsessive-compulsive symptoms (OCS). In a naturalistic study following 543 patients, 38.9% of patients taking clozapine reported OCS, compared with 20.1% taking olanzapine and 23.2% taking risperidone ([Scheltema Beduin et al. 2012](#)). A report of two case studies of patients with bipolar disorder taking clozapine demonstrated clearly a temporal relationship between initiation of clozapine and OCS ([Lemke and Bustillo 2013](#)). [Schirmbeck and Zink \(2012\)](#)

recommend reduction of clozapine dose after augmentation with a mood stabilizer and possibly crossover to or addition of a non-OCD-inducing antipsychotic; however, there is no evidence as yet to support these approaches.

Although this daunting array of side effects—along with the management of the risk of agranulocytosis—makes the treatment of patients with clozapine complex, it is common for patients to report a sense of relief from the dysphoric moods they experienced while taking conventional antipsychotics. Additionally, the freedom from EPS may account for the enhanced sense of well-being in patients treated with clozapine.

## Discontinuation and Reinitiation (Rechallenge)

As summarized in their 2013 review, Nielsen et al. posit that clozapine should be discontinued in all cases of agranulocytosis ( $\text{ANC} < 500/\text{mm}^3$ ), myocarditis, and cardiomyopathy and not discontinued for known benign side effects such as eosinophilia, benign neutrophilia or leukocytosis, idiopathic sinus tachycardia, or benign hyperthermia (Nielsen et al. 2013). Seizures should not be an absolute contraindication to clozapine treatment, because they may be managed by initiation of an anticonvulsant either prophylactically prior to initiation of clozapine or by stabilization of seizures prior to initiation of clozapine.

Historically, if a patient's WBC count decreased below  $2,000/\text{mm}^3$  or their ANC decreased below  $1,000/\text{mm}^3$ , clozapine was discontinued and the patient was regarded as nonrechallengeable; that is, reinitiation of clozapine

should not be attempted. With new FDA regulations implemented in October 2015, clinicians were given the freedom to evaluate each patient on a case-by-case basis and to weigh the relative risk of psychosis with risk of agranulocytosis. If and when a clinician opts to restart clozapine in any patient, regardless of the circumstance, they must begin at 12.5 mg orally once or twice daily and titrate upward gradually. If the patient has not experienced adverse effects from clozapine in the past, the reinitiation dose may be titrated upward more rapidly than their initial titration.

---

## Drug-Drug Interactions

---

As mentioned in the section “Pharmacokinetics and Disposition,” clozapine is predominately metabolized by CYP1A2, although CYP2D6 and CYP3A3/4 also contribute to its metabolism (Buur-Rasmussen and Brøsen 1999). Smoking, which induces CYP1A2, lowers clozapine plasma levels, and up to two times normal doses of clozapine may be required to maintain a therapeutic serum level. Fluvoxamine and ciprofloxacin, potent inhibitors of CYP1A2, dramatically increase plasma levels of clozapine (Heeringa et al. 1999; see also the FDA table “Drug Development and Drug Interactions: Table of Substrates, Inhibitors and Inducers” at [www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources/DrugInteractionsLabeling/ucm093664.htm](http://www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources/DrugInteractionsLabeling/ucm093664.htm)), and on occasion, adverse effects are seen (Koponen et al. 1996). Other reports suggest that inhibitors of CYP2D6, including paroxetine and fluoxetine, can elevate clozapine

levels ([Joos et al. 1997](#); [Spina et al. 1998](#)). In general, if the patient initiates a strong CYP1A2 inhibitor, use one-third of their normal dose. For moderate or weak CYP1A2 inhibitors, or CYP2D6 or CYP3A3/4 inhibitors, consider decreasing their dose. If they initiate strong CYP3A3/4 inducers, or moderate or weak CYP1A2 inducers, monitor for decreased effectiveness and consider increasing their clozapine dose if necessary. Cytochrome-related problems can be avoided by monitoring clozapine plasma levels while gradually increasing clozapine from a low starting dose.

---

## Conclusion

---

Clozapine maintains an important place in the treatment of severe psychosis. Side effects, including agranulocytosis, cardiomyopathy, seizures, sedation, and weight gain, make it the most difficult antipsychotic to prescribe. For this reason, clozapine should be reserved for patients who have not responded to one or more other antipsychotics. On the whole, however, this very effective treatment is underutilized in most communities. This is unfortunate, because patients' conditions should never be labeled treatment refractory or patients deemed partial responders until they have received an adequate trial of clozapine.

# CHAPTER 26

## Olanzapine

Amy L. Silberschmidt, M.D.

Jacob S. Ballon, M.D., M.P.H.

S. Charles Schulz, M.D.

---

### History and Discovery

---

The story of specific antipsychotic medications for patients with schizophrenia and other severe psychiatric illnesses began in the early 1950s, when chlorpromazine was first given to psychotic patients in France ([Delay and Bernitzer 1952](#)). The antipsychotic qualities of this compound, as well as its “tranquilizing” effect, were dramatic and substantial. Studies performed around the world during the 1950s showed the usefulness of this new compound and of the others that followed. As is well known, multicenter trials of antipsychotic medications found that the approved medications were substantially and significantly better than placebo ([Guttmacher et al. 1964](#)). Furthermore, despite the range of chemical structures, the clinical effects were

similar. In addition, the need to investigate the new medications for psychiatric illness led to improved clinical trial methodology for the field. During the 1960s, randomized and placebo-controlled trials became the standard for assessing the new medications for schizophrenia. These trials led to adoption of antipsychotic medications as the standard somatic treatment for schizophrenia.

However, over time, the adverse effects of these medications began to be recognized as more troublesome (Table 26-1). For example, many patients complained of medication-induced parkinsonism, dystonias, slowed thinking, blunted affect, akathisia, and tardive dyskinesia. These side effects were uncomfortable for patients taking the medications and, in many cases, led to poor treatment adherence.

---

**TABLE 26-1.    Shortcomings of traditional antipsychotic medications**

---

Significant response in only 60%–70% of patients
Movement disorder side effects
Dystonia
Parkinsonism
Tardive dyskinesia
Akathisia
Slowed thinking (“cognitive parkinsonism”)
Secondary negative symptoms

---

Looking for ways to achieve the same treatment benefit with fewer side effects, investigators at Eli Lilly began to screen numerous compounds for potentially useful

psychotropic properties. In 1990, the company applied for and received a patent for the compound olanzapine. It is interesting to note that the new compound had many structural similarities to clozapine, which in 1989 had been approved for use in treating refractory schizophrenia. Hailed as a novel second-generation antipsychotic drug, clozapine was thought to have potential for schizophrenia, mania, and anxiety. Clozapine was noted for its efficacy as well as its freedom from neurological side effects.

Olanzapine was first given to patients with schizophrenia in 1995 ([Baldwin and Montgomery 1995](#)). The patients in the study experienced a substantial decrease in their symptoms while receiving 5–30 mg/day of the compound. The study researchers noted a low degree of extrapyramidal side effects (EPS), although concern was raised regarding elevation of liver enzymes, as one patient had to discontinue the study for that reason.

The initial testing of olanzapine had useful results and led to a program of three pivotal trials of the drug. These first three controlled studies compared olanzapine (at two fixed dosages: 1 mg/day and 10 mg/day) against placebo ([Beasley et al. 1996a](#)); olanzapine at three fixed dosages (low, medium, or high) against olanzapine at 1.0 mg/day or haloperidol at 15 mg/day or placebo ([Beasley et al. 1996b](#)); and olanzapine against haloperidol in a large international study ([Tollefson et al. 1997](#)). The positive results for olanzapine led to U.S. Food and Drug Administration (FDA) approval in 1997 and subsequent widespread use in the United States and around the world.

---

## Structure-Activity Relations

---

Olanzapine is a thienobenzodiazepine derivative that bears a close structural resemblance to clozapine. The formal chemical name of olanzapine is 2-methyl-4-(4-methyl-1-piperazinyl)-10*H*-thieno[2,3-*b*] [1,5]benzodiazepine. Structurally, olanzapine differs from clozapine by two additional methyl groups and the lack of a chloride moiety (Figure 26-1). The in vitro receptor binding profiles of olanzapine and clozapine are relatively similar. According to the package insert, olanzapine is known to have a high affinity for dopaminergic ( $D_{1-4}$ ), serotonergic (5-HT<sub>2A/2C</sub>, 5-HT<sub>6</sub>), histaminergic ( $H_1$ ), and  $\alpha$ -adrenergic ( $\alpha_1$ ) receptors, with moderate affinity for muscarinic ( $M_{1-5}$ ) receptors and weak activity at benzodiazepine,  $\gamma$ -amino-butyric acid type A (GABA<sub>A</sub>), and  $\beta$ -adrenergic receptors (Eli Lilly 2015).

**FIGURE 26-1.** Chemical structure of olanzapine.

---

## Pharmacological Profile

---

In vitro and preclinical behavioral studies of olanzapine predicted significant antipsychotic activity with a low propensity to induce EPS. Because clozapine is the

prototype for second-generation antipsychotic action, it serves as the yardstick for “atypicality” of comparator compounds. Despite widespread general use of the term *atypical* to refer to any antipsychotic developed after clozapine, the term was originally coined to connote medications with an EPS risk no greater than that of placebo. While it is true that olanzapine carries a lower risk of tardive dyskinesia than do many other antipsychotics, its risk is still appreciably greater than that of placebo, and therefore the term *atypical* does not apply ([Farah 2013](#)).

One property that may lower a compound’s risk of EPS is nonselective binding of dopamine receptors. Classical antipsychotics selectively block dopamine D<sub>2</sub>-like (D<sub>2</sub>, D<sub>3</sub>, and D<sub>4</sub>) receptors over D<sub>1</sub>-like (D<sub>1</sub> and D<sub>5</sub>) receptors—for example, haloperidol has a D<sub>2</sub>-to-D<sub>1</sub> binding ratio of 25:1. Clozapine nonselectively binds all five dopamine receptor subtypes, with a D<sub>2</sub>-to-D<sub>1</sub> ratio of 0.7:1, whereas olanzapine is only partially selective for the D<sub>2</sub>-like group, with a D<sub>2</sub>-to-D<sub>1</sub> ratio of approximately 3:1, intermediate between those of haloperidol and clozapine.

In animal models predictive of antipsychotic efficacy, olanzapine produces effects indicating dopamine antagonism, with a low propensity to produce EPS. For example, in rats, olanzapine reduces climbing behavior induced by apomorphine and antagonizes stimulant-induced hyperactivity, both characteristic of antipsychotic effects. The ratio of the dose needed to produce catalepsy to the dose needed to inhibit conditioned avoidance, another model for atypical efficacy, is higher for olanzapine than for conventional agents ([Moore 1999](#)).

Another potential mechanism whereby dopamine antagonists may exert antipsychotic effects with minimal

EPS is through selective activity in the A10 dopaminergic tracts from the ventral tegmentum to mesolimbic areas compared with effects antagonizing the A9 nigrostriatal projections that mediate EPS. Olanzapine in chronic administration, like clozapine, selectively inhibits firing of A10 neurons without significant inhibition of A9 tracts ([Stockton and Rasmussen 1996a](#)). Olanzapine shows increased c-fos activity in the nucleus accumbens relative to the dorsolateral striatum, thus demonstrating selective blockade of the mesolimbic dopamine tract compared with the nigrostriatal tract ([Robertson and Fibiger 1996](#)).

A leading theory regarding atypicality relates to the fleeting effects of atypical antipsychotics at the D<sub>2</sub> receptor, coupled with regional selectivity of these compounds ([Seeman 2002](#)). Olanzapine's D<sub>2</sub> receptor occupancy saturation—which has been shown to be intermediate between that of clozapine and that of haloperidol—may be responsible for its decreased risk of EPS ([Tauscher et al. 1999](#)). However, because the current second-generation antipsychotic medications have substantially differing effects at many of the targets thought to play a role in atypicality, there is not yet consensus regarding the true rationale for atypicality in these agents compared with the first-generation antipsychotics ([Farah 2005](#)).

Amphetamine administration in rats is often used as a model for psychosis. The sympathomimetic activity and dopamine release provide a target for testing antipsychotic medications. Olanzapine disrupts the activity of amphetamines in rats ([Gosselin et al. 1996](#)). Olanzapine was shown in a rat model to decrease dopamine release in the A10 dopaminergic neurons of the ventral tegmentum greater than the A9 dopaminergic neurons of the striatum after chronic administration and after an amphetamine

challenge ([Stockton and Rasmussen 1996a, 1996b](#)). Olanzapine does not induce catalepsy in rats at doses needed for antipsychotic efficacy.

Another model of psychosis in rats is produced by administration of the glutamatergic *N*-methyl-D-aspartate (NMDA) receptor antagonist phencyclidine (PCP). Chronic PCP use in humans is associated with symptoms similar to those in schizophrenia, including negative symptoms, thus making it a putative model for schizophrenia ([Krystal et al. 1994](#)). Olanzapine has been shown to decrease the hyperactivity of NMDA receptors under chronic PCP administration, which may have a bearing on its effect on negative symptoms ([Ninan et al. 2003](#)). With chronic administration, glutamatergic activity continues to be affected by olanzapine ([Jardemark et al. 2000](#)). Despite these findings, olanzapine has no direct affinity for the NMDA receptor ([Stephenson and Pilowsky 1999](#)).

Receptor-binding studies show that olanzapine has a broad range of neurotransmitter effects ([Bymaster et al. 1996](#)). Although olanzapine has potent muscarinic  $M_{1-5}$  receptor affinity in vitro (another contributor to putative anti-EPS effects), in practice few olanzapine-treated patients have anticholinergic side effects that are clinically significant.  $\alpha_1$ -Adrenergic and  $H_1$  histaminergic antagonism contribute to olanzapine's adverse-effect profile of orthostatic hypotension ( $\alpha_1$ ), sedation ( $H_1$ ), and possibly weight gain ( $H_1$ ). Olanzapine, like other second-generation antipsychotics, has a higher affinity for 5-HT<sub>2</sub> receptors than for D<sub>2</sub> receptors ([Kapur et al. 1999](#)). There is also indirect evidence that olanzapine blocks 5-HT<sub>2C</sub> receptors ([Sharpley et al. 2000](#)). Olanzapine has little or no effect on

$\alpha_2$ - and  $\beta$ -adrenergic,  $H_2$ , nicotinic, GABA, opioid, sigma, or benzodiazepine receptors.

---

## Pharmacokinetics and Disposition

---

Olanzapine is well absorbed after oral administration, with peak concentrations typically occurring 4–6 hours after ingestion ([Kassahun et al. 1997](#)). Approximately 40% of a given dose undergoes first-pass metabolism and therefore does not reach the systemic circulation, and food has little effect on olanzapine's bioavailability ([Callaghan et al. 1999](#); [Eli Lilly 2015](#); [Kassahun et al. 1997](#)).

Two bioequivalent oral formulations of olanzapine are currently available: a standard oral tablet and an oral disintegrating tablet. The oral disintegrating tablets are intended for swallowing and absorption through the gut; however, sublingual administration has also been favored by some, as it allows the clinician to verify that the medication was taken. [Markowitz et al. \(2006\)](#) discovered that although the oral disintegrating preparation of olanzapine is absorbed more quickly than the standard oral tablet, this preparation's onset of effect is approximately the same regardless of whether it is taken sublingually or conventionally swallowed. In either case, the onset of action with the oral dissolving tablet is faster than that with the standard oral tablet. After a 12.5-mg oral dose of  $^{14}\text{C}$ -labeled olanzapine, approximately 57% of the radiocarbon is recovered in urine and 30% in feces. In vitro studies suggest that olanzapine is approximately 93% protein

bound, binding primarily to albumin and  $\alpha_1$ -acid glycoprotein ([Kassahun et al. 1997](#)).

Olanzapine is available as an intramuscular preparation, intended for treatment of the acute agitation typically seen in schizophrenia or in acute manic episodes of bipolar disorder. The peak plasma concentration is typically reached between 15 and 45 minutes after administration. The potency of intramuscular olanzapine is nearly five times greater than that of the orally administered drug, based on plasma levels. Clinical antipsychotic onset with intramuscular olanzapine is evident within 2 hours of administration, with benefits lasting for at least 24 hours ([Kapur et al. 2005](#)).

Olanzapine is also available in a long-acting injectable (LAI) preparation composed of a dihydrate form of olanzapine pamoate. As a dihydrate molecule, it is less soluble in water than a monohydrate and thus has the longer half-life required for a depot formulation. This formulation is designed to be dosed once every 4 weeks ([Mamo et al. 2008](#)).

Finally, olanzapine is available in a combined preparation with fluoxetine. The olanzapine-fluoxetine combination (OFC) tablet provides fixed doses of olanzapine and fluoxetine. Overall, few pharmacokinetic changes result from adding fluoxetine to olanzapine, and those that do occur are generally related to cytochrome P450 (CYP) 2D6 inhibition. There is no change in the overall half-life of olanzapine. Although minor yet statistically significant changes occur in the concentration of olanzapine when it is coadministered with fluoxetine, these changes are not *clinically* significant and do not alter the side-effect profile of olanzapine ([Gossen et al. 2002](#)).

Olanzapine is extensively metabolized to multiple metabolites, but primarily to 10-*N*-glucuronide and 4'-*N*-desmethylolanzapine ([Macias et al. 1998](#)). In vitro studies assessing the oxidative metabolism of olanzapine suggest that CYP1A2 is the enzyme primarily responsible for the formation of 4'-*N*-desmethylolanzapine, flavin-containing monooxygenase-3 (FMO3) is responsible for the formation of 4'-*N*-oxide olanzapine, and CYP2D6 is the primary enzyme responsible for the formation of 2-hydroxymethyl olanzapine ([Ring et al. 1996b](#)). Although CYP1A2 appears to be a major route of metabolism, olanzapine clearance in one study was not significantly correlated with salivary paraxanthine-to-caffeine ratio (thought to be a measure of CYP1A2 activity) ([Hägg et al. 2001](#)). Another analysis, however, found that the 4'-*N*-desmethylolanzapine-to-olanzapine plasma metabolic ratio significantly correlated with olanzapine clearance ([Callaghan et al. 1999](#)). Olanzapine pharmacokinetic parameters do not differ significantly between extensive and poor metabolizers of CYP2D6 (see [Hägg et al. 2001](#)).

Olanzapine shows linear pharmacokinetics within the recommended dosage range ([Aravagiri et al. 1997](#); [Bergstrom et al. 1995](#); [Callaghan et al. 1999](#)). Mean half-life is 36 hours, mean clearance is 29.4 L/hour, mean volume of distribution is 19.2 L/kg, and area under the concentration-time curve over 24 hours ( $AUC_{0-24}$ ) is 333 ng\*hour/mL. The half-lives of the two major metabolites (4'-*N*-desmethylolanzapine and 10-*N*-glucuronide) are 92.6 and 39.6 hours, respectively ([Macias et al. 1998](#)). Other analyses also have found the mean half-life of olanzapine to be approximately 30 hours and the mean apparent clearance to be approximately 25 L/hour ([Callaghan et al. 1999](#); [Eli Lilly 2015](#); [Kassahun et al. 1997](#)). Once-daily

administration of olanzapine produces steady-state concentrations in about a week that are approximately twofold higher than concentrations after a single dose ([Callaghan et al. 1999](#)).

Clearance of olanzapine is approximately 25%–30% lower in women than in men, based on results of population pharmacokinetic analyses ([Callaghan et al. 1999](#); [Patel et al. 1995, 1996](#)). A study of 20 male and 7 female patients with schizophrenia receiving olanzapine also found that women had higher trough concentrations after receiving 1 week of olanzapine 12.5 mg/day ([Kelly et al. 1999](#)). Despite the differences in clearance and plasma levels, there is no difference between sexes in the incidence of EPS or other movement disorders ([Aichhorn et al. 2006](#)).

Olanzapine's pharmacokinetics in the elderly and in children differ from those in adults. In the elderly, olanzapine clearance is approximately 30% lower than in younger individuals, and the half-life is approximately 50% longer ([Callaghan et al. 1999](#); [Patel et al. 1995](#)). A study of eight children and adolescents (ages 10–18 years) found pharmacokinetic parameters similar to those reported in nonsmoking adults, with an average  $T_{\max}$  (time required to reach the maximal plasma concentration) of 4.7 hours, an average apparent oral clearance of 9.6 L/hour, and an average half-life of 37.2 hours ([Grothe et al. 2000](#)). The highest concentrations were seen when smaller-sized patients received dosages greater than 10 mg/day; therefore, dosing should take into consideration the size of the child.

Impairment in either hepatic or renal function has not been associated with altered olanzapine disposition. In a study of four healthy individuals and eight patients with hepatic cirrhosis, no significant differences in olanzapine

pharmacokinetics were found, although urinary concentrations of olanzapine 10-*N*-glucuronide were increased in patients with cirrhosis ([Callaghan et al. 1999](#)). A study comparing olanzapine pharmacokinetics in six subjects with normal renal function, six subjects with renal failure who received an olanzapine dose 1 hour before hemodialysis, and six subjects with renal failure who received an olanzapine dose during their 48-hour interdialytic interval did not find any significant differences. These data suggest that olanzapine dosage does not need to be adjusted in patients with renal or hepatic disease ([Callaghan et al. 1999](#)).

---

## Mechanism of Action

---

In discussing olanzapine's mechanism of action in the treatment of schizophrenia, it should be noted that there is no established molecular mechanism that can unify the symptoms of schizophrenia. No precise animal or in vitro model for the illness exists, nor is there a consensus on its precise etiology or pathophysiology. Numerous neurochemical hypotheses have been proposed, including theories implicating abnormalities in dopaminergic, glutamatergic, serotonergic, and other systems, such as neurotensin ([Boules et al. 2007](#)) or neuregulin ([Benzel et al. 2007](#)). However, the discovery that multiple receptor types exist for each neurotransmitter has added many layers of complexity to the search for explanations regarding the root causes of schizophrenia. Thus, it is no longer possible to use broad terms such as "increased dopamine" when discussing ideas about the etiology of the disorder.

Despite the caveats mentioned above regarding our rudimentary knowledge of the nature of schizophrenia, it is important to note that all approved antipsychotic medications have a significant effect on the dopaminergic system, largely through the blockade of D<sub>2</sub> receptors ([Kapur and Remington 2001](#)). Even though there are substantial differences in D<sub>2</sub> receptor affinity among the traditional antipsychotics and the second-generation antipsychotics, they all are either full antagonists or partial agonists at the dopamine D<sub>2</sub> receptor. Of interest is evolving research indicating the importance of multiple-receptor blockade to the effectiveness of the second-generation antipsychotic class. As the various neurotransmitter systems have been investigated in the neuropsychopharmacology of schizophrenia, evidence is emerging that the second-generation antipsychotics, and olanzapine in particular, may improve different schizophrenia symptom domains by means of effects on 5-HT receptors, on multiple-receptor binding, on region-specific and more fleeting binding to dopamine receptors, on glutamate neurotransmission, and perhaps on neuropeptide neurotransmitters. In the following paragraphs, we discuss each of these specific ideas about olanzapine's mechanism of action in turn.

In clinical investigations with positron emission tomography (PET) imaging, [Kapur et al. \(1998\)](#) showed that olanzapine at a wide range of dosages blocks a high percentage (95% or greater) of 5-HT<sub>2A</sub> receptors and also blocks dopamine receptors in a dose-dependent fashion—crossing the putative antipsychotic blockade line at dosages commonly used to diminish psychotic symptoms of schizophrenia. This study indicated that olanzapine's

primary mechanism was related to the blockade of dopamine receptors and additionally noted that olanzapine showed stronger affinity for 5-HT<sub>2A</sub> receptors than for dopamine receptors at all dosage ranges.

A more compelling hypothesis regarding the mechanism of olanzapine's effects emerged from in vivo PET scanning work performed in a series of experiments at the University of Toronto and in Sweden. Results of the initial PET scanning studies of patients receiving clozapine indicated that atypical dopamine D<sub>2</sub> receptor binding was occurring ([Farde and Nordström 1992](#); [Farde et al. 1992](#); [Kapur et al. 2000](#)). The group subsequently found similar unusual D<sub>2</sub> receptor binding with quetiapine and, to some degree, olanzapine ([Kapur et al. 1998](#)). The authors proposed that the so-called atypical antipsychotic effect—successful treatment of psychotic symptoms without induction of movement disorder side effects—may be the result of a “fast off” property of some second-generation agents, wherein the drug blocks the dopamine D<sub>2</sub> receptor but leaves it quickly, a receptor occupancy pattern that effectively decreases psychosis yet causes minimal interference to the body's own dopamine receptor activity. Thus, for olanzapine, this mechanism might help explain how the drug can exert strong therapeutic effects on schizophrenia symptoms yet cause few EPS at standard dosages. From a clinical viewpoint, it is important to note that at higher olanzapine dosages (30 mg/day), greater dopamine receptor blockade is seen, and movement disorder side effects, such as akathisia, are more likely to occur.

Over the past 30 years, there has been substantial interest in the role of glutamate, an excitatory

neurotransmitter, in the pathophysiology of schizophrenia (see, e.g., [Coyle 2006](#); [Kim et al. 1980](#); [Krystal et al. 1994](#); [Moghaddam and Javitt 2012](#)). Glutamate's inclusion in theories about the development of schizophrenia is supported by the psychotomimetic properties of glutamate antagonists such as PCP and ketamine. These NMDA receptor antagonists induce a group of behaviors that often show closer parallels to schizophrenia than do those induced by dopamine sympathomimetic agents, in both mice and humans. Clinical trial evidence points to the potential usefulness of glutamatergic agonists (e.g., D-cycloserine) in treating schizophrenia ([Kantrowitz et al. 2010](#)). One way of examining the potential effectiveness of medication is to look at changes in deficits in *prepulse inhibition* (i.e., attenuation of the startle response), a measure of sensory motor gating that is diminished in patients with schizophrenia and can be similarly diminished pharmacologically through administration of PCP ([Dulawa and Geyer 1996](#)). In a study of rats with isolation-induced disruption of prepulse inhibition, both quetiapine and olanzapine successfully reversed the prepulse inhibition deficit ([Bakshi et al. 1998](#)).

Neurotensin receptors are collocated with and modulate mesolimbic dopaminergic neurons ([Boules et al. 2014](#)). Cerebrospinal fluid (CSF) concentrations of neurotensin are abnormal in some untreated patients with schizophrenia and have been found to normalize with antipsychotic administration. The degree of clinical improvement, particularly in negative symptoms, was found to correlate with the degree of increase in CSF neurotensin ([Sharma et al. 1997](#)). In rats, olanzapine administration was shown to increase extracellular neurotensin in the ventral striatum and medial prefrontal cortex acutely. Over time, chronic

olanzapine administration decreased the concentration of neurotensin in the medial prefrontal cortex but increased the concentration in the ventral striatum. Furthermore, chronic olanzapine administration abolished the stimulatory effects of amphetamine administration in these regions ([Gruber et al. 2011](#)). Olanzapine does not bind to the neurotensin 1 (NT<sub>1</sub>) receptor in humans ([Theisen et al. 2007](#)) but may influence neurotensin through its action on other subtypes of neurotensin receptor or its downstream effects.

Neuregulins are a family of growth factors that stimulate the ERbB receptor tyrosine kinases and have been shown to play a role in the assembly of neural circuitry, myelination, neurotransmission, and synaptic plasticity. The neuregulin-1 gene (*NRG1*) has been associated with schizophrenia in several large genomewide association studies and meta-analyses ([Mei and Nave 2014](#)). In rats, (*NRG1*) expression increases in the hippocampus after 1 week of olanzapine administration; however, after 12 weeks, its expression decreases in the prefrontal cortex and cingulate cortex ([Deng et al. 2015](#)). In a study using immortalized lymphocytes from schizophrenia patients and control subjects from unrelated families, expression of the *NRG1* glial growth factor isoform was found to be lower in schizophrenia patients than in control subjects, both before and after stimulation with olanzapine ([Chagnon et al. 2008](#)).

In summary, olanzapine works at least at the dopamine, 5-HT, and glutamate receptors. There is intriguing circumstantial evidence that olanzapine may modulate neurotensin and neuregulin. Current theories suggest that dopamine receptor-blocking capabilities are a necessary but not sufficient requirement for antipsychotic

effectiveness. The other studied mechanisms, when taken in total, may be the factors leading to olanzapine's broad efficacy and side-effect profile.

---

## Indications and Efficacy

---

Olanzapine initially received FDA approval for the treatment of psychosis. Currently, it has multiple indications, including treatment of schizophrenia; acute treatment of manic or mixed states in bipolar disorder; and maintenance treatment of bipolar disorder, both as monotherapy and as an adjunct to mood stabilizer therapy. The OFC preparation has an FDA indication for bipolar depression and treatment-resistant depression. Intramuscular olanzapine carries an indication for acute agitation in schizophrenia and bipolar mania. Olanzapine is approved for adults and for children ages 13–18 years.

In addition to the approved indications, olanzapine has been studied—and at times used with limited evidence—in several other illnesses. In this section, we present the evidence base supporting the use of olanzapine for its FDA-indicated uses as well as for off-label uses.

## Approved Indications

### Schizophrenia

As noted earlier, olanzapine was originally developed as a medication with potential for treating schizophrenia, mania, and anxiety. To gain FDA approval for the treatment of schizophrenia, olanzapine was tested in four pivotal studies

to assess the compound for efficacy, safety, and dosage range. The earliest testing of olanzapine was an assessment of olanzapine dosages of 5–30 mg/day following an initial starting dosage of 10 mg/day. Brief Psychiatric Rating Scale (BPRS) scores were reduced substantially, and EPS incidence was low ([Baldwin and Montgomery 1995](#)). These encouraging results led to further studies and pointed to a dosage range to be tested.

**Efficacy studies.** The first pivotal study compared two dosages of olanzapine (1 mg/day and 10 mg/day) with placebo in a large international sample. The 10 mg/day dosage was statistically significantly superior to placebo on objective rating scales ([Beasley et al. 1996a](#)). The second pivotal study was a dose-ranging comparison of olanzapine versus haloperidol and placebo, also in a large international sample. Three dosage ranges for olanzapine were included: 1) low ( $5 \pm 2.5$  mg/day), 2) medium ( $10 \pm 2.5$  mg/day), and 3) high ( $15 \pm 2.5$  mg/day). Haloperidol was dosed to  $15 \pm 2.5$  mg/day. Olanzapine at the medium and high dosage ranges and haloperidol were associated with significant improvements compared with placebo ([Beasley et al. 1996b](#)). [Beasley et al. \(1997\)](#), using the same sample, further demonstrated that acute EPS were reported less frequently in all olanzapine dosage groups than in the haloperidol group. [Tollefson and Sanger \(1997\)](#) re-analyzed data from the first two studies and found that olanzapine had a direct therapeutic effect on negative symptoms that was not mediated by its effects on positive symptoms, EPS, or mood.

Another large international multicenter trial used a flexible dosing strategy to show olanzapine's clinical superiority to haloperidol on positive symptoms, negative

symptoms, comorbid depression, EPS, and overall drug safety. In this study, patients were started on olanzapine or haloperidol at dosages ranging from 5 to 20 mg/day. Ultimately, patients received olanzapine 13.2 mg/day compared with haloperidol 11.8 mg/day ([Tollefson et al. 1997](#)).

The group of studies described above led to olanzapine's approval for psychosis (later changed to schizophrenia). Several other studies have confirmed olanzapine's efficacy in the treatment of schizophrenia. With its added benefit of low movement disorder side effects, olanzapine has become an important addition to the armamentarium of the psychiatrist treating schizophrenia. [Leucht et al. \(1999\)](#) reported that olanzapine was statistically more effective than placebo (moderate effect) and also more effective than haloperidol (small effect) on global schizophrenia symptomatology.

A large National Institute of Mental Health (NIMH)-funded investigation sought to compare the second-generation antipsychotics olanzapine, risperidone, quetiapine, and ziprasidone with perphenazine in order to understand the efficacy and side-effect profiles of the newer versus older antipsychotic medications ([Lieberman et al. 2005](#)). This project, the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE), was designed to provide a double-blind yet reasonably naturalistic setting for clinicians to treat patients, using time to discontinuation for any reason as the primary outcome variable. Although olanzapine had the longest time to all-cause discontinuation of any medication in the trial, it also had the highest rate of discontinuation due to metabolic complications such as weight gain, whereas perphenazine had the highest rate of discontinuation due to EPS. Overall, however, the

discontinuation rate was high for all medications, with nearly 75% of patients changing medications within the 18-month study duration. Much discussion and written commentary has ensued since the initial findings were published, including analyses of cost-effectiveness ([Rosenheck et al. 2006](#)), of the effects of antipsychotic medication on psychosocial functioning ([Swartz et al. 2007](#)), and of the impact of switching medications ([Essock et al. 2006](#)), as well as numerous editorials about the treatment implications of the study.

Schizophrenia is often not fully responsive to antipsychotic treatment. Assessment of olanzapine in patients with treatment-refractory illness did not support its usefulness in a stringent nonresponder protocol ([Conley et al. 1998](#)). However, in an Eli Lilly-sponsored double-blind noninferiority multicenter trial, olanzapine's effect in lowering Positive and Negative Syndrome Scale (PANSS) scores was comparable to that of clozapine ([Tollefson et al. 2001](#)). A second phase of the CATIE project examined the use of clozapine in patients with treatment-refractory illness and found, based on the time to discontinuation, that clozapine was a superior treatment for patients who had not responded to other second-generation medications ([McEvoy et al. 2006](#)).

Although early research noted olanzapine's beneficial effects on negative symptoms and cognitive symptoms of schizophrenia, these effects were not as strong as the drug's effects on positive symptoms. Olanzapine's efficacy in negative symptoms was first reported by [Tollefson et al. \(1997\)](#) following completion of a large double-blind trial of olanzapine and haloperidol. When all symptom improvements were taken into account, olanzapine-treated subjects showed greater improvement than haloperidol-

treated patients in negative symptoms (as measured by improvement in scores on both the Scale for the Assessment of Negative Symptoms [SANS] and the BPRS negative symptom subscale). In a flexible-dose comparison between risperidone and olanzapine in patients followed for 1 year, olanzapine-treated patients showed significantly greater improvement on SANS scores than did risperidone-treated patients ([Alvarez et al. 2006](#)). Interestingly, in a study by researchers from Eli Lilly that followed patients taking either quetiapine or olanzapine for 6 months, the two groups showed similar improvements on the SANS at study completion ([Kinon et al. 2006](#)). In a meta-analysis of 50 studies of second-generation antipsychotics ([Komossa et al. 2010](#)), no difference in short-, medium-, or long-term improvement of negative symptoms (as measured by PANSS negative, BPRS negative, and/or SANS total scores) was found between olanzapine and the other medications, which included amisulpride, clozapine (1 of 12 studies found clozapine to be superior as measured by SANS total scores), quetiapine, and ziprasidone (1 of 2 studies found olanzapine to be superior on PANSS negative scores, but overall no difference was found). The same study found olanzapine to outperform risperidone on improvement of negative symptoms (as measured by SANS total score) ([Komossa et al. 2010](#)).

Cognitive functioning is the most important indicator of schizophrenia prognosis ([Green 2006](#)). In a 1-year comparison of olanzapine with risperidone, both groups showed modest benefits on a cognitive function battery ([Gurpegui et al. 2007](#)). In a study conducted over a 1-year period by Eli Lilly researchers in Spain, olanzapine-treated patients showed greater benefit in social functioning than did risperidone-treated patients, as assessed by scores on

the Social Functioning Scale (SFS). The greatest difference was in occupation/employment, but improvements were also seen on measures of independence, social engagement, and recreation ([Ciudad et al. 2006](#)).

In an 8-week double-blind, placebo-controlled study, the LAI formulation of olanzapine showed a statistically significant separation from placebo (as measured by decreases in PANSS total scores) that was evident by day 7 ([Lauriello et al. 2008](#)). Another study of olanzapine LAI that involved a longer period of treatment—24 weeks—found that a high percentage of subjects remained free of psychotic exacerbation ([Kane et al. 2010](#)). The published report of this study also discussed the relationship between oral and LAI olanzapine dosing and noted that the potential for accidental intravascular injection—which can cause sedation and/or delirium—requires that patients be observed for 3 hours after injection.

Studies have investigated olanzapine's efficacy in the treatment of schizophrenia spectrum and other psychotic disorders in adolescents. In a systematic review of the literature in children, second-generation antipsychotics were shown to be beneficial overall in improving psychotic symptoms ([Jensen et al. 2007](#)). Olanzapine's safety profile in adolescents is similar to its profile in adults, although its adverse effects on weight and prolactin are more significant in young people ([Kryzhanovskaya et al. 2009a](#)). A double-blind, flexible-dose study demonstrated comparable efficacy for risperidone, olanzapine, and haloperidol in psychotic young people ([Sikich et al. 2004](#)). A similar trial of olanzapine, risperidone, and quetiapine in early psychosis found equivalent rates of discontinuation for the three drugs over a 52-week period, with olanzapine and risperidone showing slightly greater reductions on PANSS

positive scores compared with quetiapine ([McEvoy et al. 2007](#)). In late 2009, olanzapine received FDA approval for the treatment of schizophrenia in teenagers, but with the recommendation that clinicians first consider the use of other agents, given concerns about metabolic consequences (for further discussion, see section titled “Side Effects and Toxicology” later in this chapter).

Studies have shown that approximately 25% of individuals with early signs of schizophrenia will ultimately develop the disease, although in the past, rates of conversion were estimated as being much higher (40%–50%; see [Kaur and Cadenhead 2010](#) for a review). Olanzapine’s use in a population considered to be at high risk for schizophrenia but not meeting full symptom criteria was evaluated in a double-blind multicenter study ([McGlashan et al. 2006](#)). The olanzapine group did not show statistically significant reductions in the rate of conversion to psychosis compared with the placebo group. However, a number of factors, including high dropout rates in both groups, the lack of a systematic method for diagnosing clinical psychiatric disorders, and problems regarding selection and classification of patients, limited the generalizability and reliability of the findings ([McGlashan et al. 2006](#)). The number needed to treat (NNT), a measure of effect size, was 4.5 in this study; thus, whereas early treatment with olanzapine may benefit some individuals, the increased risk of metabolic side effects associated with use of antipsychotics in adolescents mandates that an abundance of caution be exercised before making the decision to administer these medications to young people who are not yet ill. Olanzapine treatment was not found to improve cognition in adolescents identified as being at risk of psychosis, and olanzapine treatment did not significantly

alter neuropsychological deficits either at baseline or after conversion to psychosis ([Hawkins et al. 2008](#)). Given the long-term side-effect consequences, antipsychotic medication is not indicated in people with subthreshold levels of psychosis.

At the other end of the age spectrum, olanzapine has been investigated in the treatment of psychotic disorders in the elderly. Olanzapine, like all antipsychotic medications, carries an FDA black box warning regarding an increased risk of stroke associated with its use in elderly individuals with dementia-related psychosis. (The use of olanzapine in dementia is discussed in greater detail in a separate subsection; see “Dementia-Related Agitation and Psychosis” later in this chapter.) A study of olanzapine versus haloperidol in a group of older patients with chronic schizophrenia found a statistical advantage for olanzapine ([Barak et al. 2002](#)). In a study of olanzapine in 94 acutely ill inpatients age 65 years or older, some with psychosis, [Hwang et al. \(2003\)](#) reported mean reductions from baseline of greater than 50% on BPRS scores, thus illustrating olanzapine’s usefulness in treating a broad range of psychotic symptoms in older patients. As with any treatment used in elderly persons, special care must be taken to avoid cardiovascular complications. With olanzapine, orthostatic hypotension, oversedation, and thus the risk of falls must be factored into the dosing decision ([Gareri et al. 2006](#)).

**Treatment approaches.** Early studies of olanzapine assessed dosages ranging from 5 to 30 mg/day. When olanzapine was initially released, it was recommended that the medication be started at a dosage of 10 mg/day, often given as a bedtime dose. Subsequently, clinicians have used

average dosages higher than 10 mg/day (e.g., approximately 13 mg/day). In the flexible-dosing segment of CATIE, in which the available dosages were 7.5, 15.0, 22.5, and 30.0 mg/day), the average dosage was 20.1 mg/day ([Lieberman et al. 2005](#)). For inpatient treatment, clinicians often will give patients 5 mg of olanzapine in the morning and 10 mg at bedtime ([Schulz 1999](#)). Because some patients appear to have an inadequate response to olanzapine at the recommended dosages, clinicians have assessed the usefulness of olanzapine at dosages above the recommended 20 mg/day. Many hospital clinicians employ a loading strategy with olanzapine, particularly in patients presenting with acute agitation, using dosages up to 40 mg/day for the first 2 days and gradually decreasing to a target dosage of 20–30 mg/day ([Baker et al. 2003](#); [Brooks et al. 2008](#)). Although sedation and hypotension must be watched for in any individual patient, increased rates of those side effects were not seen in a study comparing the loading-dose strategy with conventional 10-mg/day dosing ([Baker et al. 2003](#)).

Typically, agitated patients are best treated with the rapid-dissolving preparation of olanzapine. Given its faster onset of action and the decreased risk of “cheeking” of medication, the rapid-dissolving tablet formulation is preferable to the conventional pill in the acute setting, particularly when some sedation is also needed. When patients are severely agitated, use of injectable olanzapine is often necessary. The intramuscular preparation has a rapid onset of action, similar to that of dissolvable tablets, as well as a certainty of delivery that is imperative in an emergency. The injectable preparation has been shown to be superior to placebo at doses of 10 mg and as effective as haloperidol, with significantly fewer side effects ([Breier et](#)

al. 2002). However, case reports caution against use of olanzapine in conjunction with intramuscular lorazepam because of the risk of hypotension (Zacher and Roche-Desilets 2005).

For patients who require long-term treatment, olanzapine LAI can be used on a once-monthly administration schedule. Because of concerns regarding cases of delirium and even coma reported in early studies, patients receiving olanzapine LAI must be observed for 3 hours after the injection. This monitoring requirement has significantly limited the use of the LAI form.

## **Bipolar Disorder and Treatment-Resistant Depression**

Before the introduction of second-generation antipsychotic medications, it was well known that traditional antipsychotic medications were useful in the treatment of mania. Findings from a study assessing the effects of olanzapine versus haloperidol on symptoms of schizoaffective disorder provided a rationale for studying olanzapine in bipolar disorder. Compared with the schizoaffective disorder patients who received haloperidol in this study, the patients who received olanzapine showed superior outcomes on many, but not all, measures (Tran et al. 1999).

The first controlled study of olanzapine in bipolar disorder was a 21-day comparison of olanzapine with placebo (Tohen et al. 1999). Significantly greater improvement in manic symptoms (as assessed by mean change from baseline to endpoint on Young Mania Rating Scale [YMRS] total score) was observed for patients taking olanzapine compared with those taking placebo. No

difference was seen in the outcomes for depression. In this study, EPS were not more frequent in the olanzapine-treated patients than in the patients taking placebo (Tohen et al. 1999). These findings were confirmed in a second pivotal study that also showed an advantage for olanzapine over placebo (Tohen et al. 2000). An open-label follow-up (49 weeks) added valuable information, especially noting that decreases in YMRS scores continued. For the longer term, depression scores also improved. Importantly, for the patients who were exposed to olanzapine at a mean dosage of approximately 14 mg/day, no cases of tardive dyskinesia occurred (Sanger et al. 2001).

An important question of practical interest is how olanzapine compares with conventional mood stabilizers. In a double-blind trial conducted by Eli Lilly, olanzapine was compared with lithium in the maintenance treatment of bipolar disorder (Tohen et al. 2005). In the study, patients were stabilized on a combination of lithium and olanzapine and then randomly assigned to receive one or the other for 52 weeks. In the noninferiority analysis, olanzapine was shown to be as effective as lithium in preventing depression relapse, and in fact the olanzapine-treated patients had lower rates of mixed or manic symptom relapse than did the lithium-treated patients over the 52-week follow-up. Weight gain was higher in the olanzapine group (Tohen et al. 2005). Further studies confirmed the equivalent efficacy of olanzapine and the most widely used anticonvulsant mood stabilizer, divalproex (Tohen et al. 2002).

This line of research led to FDA approval of olanzapine for the treatment of manic symptoms. The mean dosage used in olanzapine monotherapy for mania is similar to that used in schizophrenia: 13 mg/day. For acute mania in agitated

bipolar patients, intramuscular olanzapine has been shown to be effective ([Meehan et al. 2001](#)).

The treatment of bipolar depression is often complex. Monotherapy with antidepressants is associated with an increased risk of switching into mania. Olanzapine has been shown to be efficacious in both manic and—in combination with fluoxetine (OFC)—depressive phases of bipolar illness (see [Schulz and Cornelius 2010](#) for a review). In an 8-week double-blind trial conducted by Eli Lilly, OFC was compared against olanzapine monotherapy and placebo in patients with bipolar I disorder in a depressed phase. Although both treatments were more effective than placebo, OFC was significantly more effective than olanzapine in treating depressive symptoms. OFC-treated patients showed greater improvement in mood compared with olanzapine-treated patients by the fourth week of the study ([Tohen et al. 2003](#)). Subjects' health-related quality of life improved as well ([Shi et al. 2004](#)). [Brown et al. \(2006\)](#) also compared OFC with lamotrigine in a 7-week study. Although OFC demonstrated a statistical separation from lamotrigine by the first week, it is difficult to make a full comparison in such a short study. Lamotrigine requires slow titration to minimize the risk of serious rash; thus, it was received at the target dosage (200 mg/day) only for the last 2 weeks of the study, whereas the OFC dosage could be titrated to therapeutic levels much more quickly. Although the rapid titration of OFC is helpful when a more urgent approach is required, further study is needed to determine whether OFC's greater benefits versus olanzapine monotherapy persist once lamotrigine has had an opportunity to remain at a therapeutic dose for a longer period of time. Rates of treatment-emergent mania with OFC were low and did not significantly differ from

rates with placebo or olanzapine monotherapy ([Amsterdam and Shults 2005](#); [Tohen et al. 2003](#)).

In bipolar I adolescents, [Tohen et al. \(2007\)](#) reported significantly greater improvement in mania ratings with olanzapine than with placebo. Scientists at Eli Lilly demonstrated that OFC was superior to placebo in bipolar adolescents in a double-blind randomized controlled trial ([Detke et al. 2015](#)). Side effects were similar to those in adults, although the magnitude of changes in lipids was somewhat higher and that of changes in glucose somewhat lower. Both olanzapine and OFC have been FDA approved for bipolar depression in adolescents.

OFC has been studied in treatment-refractory major depressive disorder. [Thase et al. \(2007\)](#) conducted a study comparing OFC with olanzapine or fluoxetine monotherapy in patients who had not shown adequate response to at least two prior trials of antidepressants. In the pooled analysis ([Thase et al. 2007](#)), OFC produced greater improvement versus olanzapine monotherapy or fluoxetine monotherapy (as assessed by scores on the Montgomery-Åsberg Depression Rating Scale [(MADRS])). In a double-blind trial sponsored by Eli Lilly, olanzapine, fluoxetine, OFC, and venlafaxine showed similar rates of efficacy ([Corya et al. 2006](#)).

The second-generation antipsychotic medications have found a role in treating not only mania but also depression in bipolar disorder. Olanzapine monotherapy has demonstrated efficacy in both acute and maintenance phases of bipolar disorder, and when combined with fluoxetine in the OFC formulation, it has shown benefit in treating depression in bipolar I disorder. Particularly in cases of mania in which psychosis is prominent, olanzapine is a reasonable first-line agent, although consideration must

be given to the potential for metabolic consequences. In depression, olanzapine has been studied primarily in—and is FDA approved only for—treatment-refractory illness. Given the drug’s metabolic side-effect profile, it is appropriate to restrict its use to cases of resistant depression.

## Off-Label Uses

### **Dementia-Related Agitation and Psychosis**

Olanzapine does not have an FDA-approved indication for the treatment of dementia. Because elderly people are generally more sensitive to the EPS and tardive dyskinesia associated with first-generation antipsychotic medications, the second-generation medications are often preferred when antipsychotics are needed.

A large placebo-controlled trial of olanzapine in Alzheimer’s patients showed that the lower dosages of olanzapine (5–10 mg/day) were significantly better than placebo in treating target symptoms of agitation, hallucinations, and delusions ([Street et al. 2000, 2001](#)). The FDA placed a black box warning on the prescribing information of antipsychotic medications calling attention to the increased risk of death, primarily from cardiovascular and infectious complications. According to the warning, second-generation antipsychotic use over a 10-week period carries a 1.6- to 1.7-fold increased risk of mortality based on data from 17 placebo-controlled trials of second-generation antipsychotics in dementia-related psychosis. Ultimately, clinical judgment and thorough documentation are important, as in certain situations the hazards of

untreated psychotic agitation may outweigh the potential risks of treatment.

Several studies have examined olanzapine in the treatment of dementia without agitation ([Brooks and Hoblyn 2007](#)). A placebo-controlled multicenter trial conducted by researchers at Eli Lilly evaluated olanzapine at low fixed dosages (1.0, 2.5, 5.0, and 7.5 mg/day) in the treatment of dementia-related psychosis ([De Deyn et al. 2004](#)). Although olanzapine did not separate from placebo on the primary outcome measure, Hallucinations and Delusions items of the Neuropsychiatric Inventory—Nursing Home edition (NPI/NH), improvements were seen in each of the dosage groups studied. All patients who received dosages of 2.5 mg/day or greater were initially started on 2.5 mg/day, with the dosage titrated upward by 2.5 mg/week (as indicated based on their assigned study group), and there was an overall difference from placebo in the acute phase of the study, suggesting that a 2.5-mg dose was an effective starting dose in the more acute setting. On some secondary outcome measures, the greatest improvement was seen with the highest olanzapine dosage (7.5 mg/day), suggesting that for some patients, an increase to 7.5 mg/day is beneficial. Because no higher dosages were used in the study, it is unclear whether continuing to increase the dosage would lead to greater efficacy ([De Deyn et al. 2004](#)).

Acetylcholine has been the focus of treatments aimed at slowing the rate of cognitive deterioration among individuals with dementia. Cholinesterase inhibitors have been used on that basis. Olanzapine may have beneficial effects on prefrontal cortex cholinergic and serotonergic neurons that may facilitate acetylcholine release to that region. However, in a double-blind study conducted by

researchers at Eli Lilly, olanzapine was shown to worsen cognitive functioning, as assessed on the Alzheimer's Disease Assessment Scale for Cognition (ADAS-Cog), and there was no statistical difference between the olanzapine and placebo groups in scores on the Clinician's Interview-Based Impression of Change (CIBIC) scale ([Kennedy et al. 2005](#)). Patients in the olanzapine group also showed cognitive worsening on the Mini-Mental State Examination (MMSE). Previous studies found little or no benefit on cognition from olanzapine treatment in nonagitated patients with dementia ([De Deyn et al. 2004](#); [Street et al. 2000](#)).

The CATIE study also had an Alzheimer's disease component in which olanzapine, risperidone, and quetiapine were compared with placebo in the treatment of psychosis and agitation in outpatients ([Schneider et al. 2006b](#)). Patients were included if they had psychotic symptoms and resided either in an assisted living facility or at home, but they were excluded if they had skilled nursing needs or primary psychotic disorders. Patients who were to receive cholinesterase inhibitors or antidepressants were also excluded from the study. As in the schizophrenia portion of CATIE, the primary outcome variable was time to discontinuation. No difference was found among the groups in time to discontinuation, and no benefit was seen on the Alzheimer's Disease Cooperative Study—Clinical Global Impression of Change (ADCS-CGIC). The average time to discontinuation ranged from 5 to 8 weeks among the treatments. Discontinuation due to lack of efficacy occurred sooner for patients receiving placebo or quetiapine than for those receiving risperidone or olanzapine. Side effects such as parkinsonism, sedation, and increased body mass index

occurred more frequently with the study medications than with placebo ([Schneider et al. 2006b](#)).

Overall, there are limited data to support the effectiveness of second-generation antipsychotics in the treatment of dementia, and the available evidence does not support olanzapine as the first choice in this medication class. Risks for worsened cognitive function and metabolic concerns must be considered when use of antipsychotic medications is contemplated. Nonetheless, there are times when behavioral consequences and patient safety require more aggressive treatment, and antipsychotic medication may be warranted. Olanzapine is considered an intermediate-risk antipsychotic in this population ([Kales et al. 2014](#)). Ultimately, a painstaking evaluation of the risk-benefit ratio of antipsychotic medication use must precede any decision to prescribe these agents, in both the acute and the long-term time frames. Further study is needed, however, regarding the use of second-generation antipsychotic medications in this population ([Schneider et al. 2006a](#)).

## **Borderline Personality Disorder**

Borderline personality disorder is a severe psychiatric illness that afflicts nearly 1% of the population ([Torgersen et al. 2001](#)). Based on earlier studies indicating that low dosages of traditional antipsychotic medications might be useful for psychosis spectrum and overall symptoms in borderline personality disorder ([Goldberg et al. 1986](#); [Soloff et al. 1986](#)), [Schulz et al. \(1999\)](#) conducted an open-label study and found that olanzapine led to substantial improvement in psychoticism, depression, interpersonal sensitivity, and anger (as measured by Hopkins Symptom Checklist-90 ratings), as well as improvement on objective

measures of impulsivity and aggression. Of the 11 women enrolled, 9 (82%) completed the study. The design of the trial allowed for early flexible dosing, and the subjects ended the 8-week trial taking olanzapine at an average dosage of approximately 7.5 mg/day, usually at bedtime. In an extension of this open-label trial, Zanarini and Frankenburg (2001) showed olanzapine's superiority to placebo over a longer (26-week) study period. This interesting study indicated that lower dosages (5 mg/day) of olanzapine can be useful in this patient population.

In a study comparing olanzapine, fluoxetine, and OFC in women with borderline personality disorder, olanzapine monotherapy was found to be more effective (as assessed on the MADRS) than either fluoxetine or OFC in treating the depressive symptoms of the disorder. Additionally, olanzapine was superior to fluoxetine in treating symptoms of impulsivity and aggression, as measured by the Overt Aggression Scale (OAS). Weight gain was seen in a greater percentage of olanzapine-treated patients than of fluoxetine-treated patients (Zanarini et al. 2004).

Two large placebo-controlled studies evaluating olanzapine in borderline personality disorder yielded mixed results. Schulz et al. (2008) reported no significant advantage for olanzapine compared with placebo in a flexible dosing design, whereas Zanarini et al. (2011) noted a statistical advantage for higher-dosage olanzapine in a fixed-dose trial comparing low-dosage olanzapine, higher-dosage olanzapine, and placebo for 12 weeks. In an open-label 12-week extension phase of the same study, Zanarini et al. (2012) found that patients who had been treated with olanzapine in the initial study maintained and continued the modest improvements in their symptoms, while patients who were treated with placebo in the initial 12 weeks and

started on olanzapine in the extension phase achieved a level of symptom relief similar to that of those who had started with olanzapine. These mixed results have led to controversy in the field about the potential use of antipsychotic medications in borderline personality disorder.

Dialectical behavioral therapy (DBT) is a mainstay of current treatment for borderline personality disorder. In a double-blind, placebo-controlled trial, olanzapine was studied as an adjunctive agent in patients receiving DBT. Impulsive and aggressive behaviors were found to be lower in the group that received olanzapine than in the placebo group. The average olanzapine dosage in the trial was 8.8 mg/day. Statistically significant increases in weight gain and dyslipidemia were observed in the olanzapine group compared with the placebo group ([Soler et al. 2005](#)). Therefore, with consideration for side effects, olanzapine may be helpful for a broader range of illnesses, particularly when used in conjunction with psychotherapy.

## **Anorexia Nervosa**

Anorexia nervosa is a common and severe psychiatric illness that may well have the highest mortality rate of any mental disorder. Severe restriction of food intake, leading to low weight, is a primary feature of the illness; however, patients also have psychotic-like disturbances in self-perceived body size or shape, as well as unusual ideas about food and metabolism. Some investigators have begun to explore the possibility that olanzapine may help with this patient group. Initial reports were largely from pilot studies, including case series, but data are now emerging from small controlled trials.

In an open-label trial, 17 patients hospitalized for anorexia nervosa were given olanzapine in conjunction with concurrent cognitive-behavioral therapy (CBT) and DBT group treatment ([Barbarich et al. 2004](#)). Olanzapine was initiated at a dosage of 1.25–5.00 mg/day, with upward titration as needed, balancing sedation and side effects against efficacy. Although patients showed improvement in weight as well as in Beck Depression Inventory (BDI) and Spielberger State-Trait Anxiety Inventory (STAI) scores, the lack of a control group limited the validity of these results ([Barbarich et al. 2004](#)). A trial of 15 women with anorexia nervosa randomly assigned to either olanzapine or chlorpromazine in a balanced block design found that olanzapine reduced anorexic ruminations (as measured by the impaired control over mental activities subscale of the Padua Inventory). There was no difference in weight gain between the two groups. However, this study was somewhat limited by its lack of blinding ([Mondraty et al. 2005](#)). A case series evaluating low-dosage olanzapine treatment in 13 adolescent girls with restricting-type anorexia nervosa ([Leggero et al. 2010](#)) found improvements in weight and reductions in hyperactivity in the 7 girls who were olanzapine responders (defined as improvement of at least 50% in Eating Attitudes Test–26 scores).

Results of randomized double-blind, placebo-controlled trials have been mixed. In a 10-week trial of 34 women with anorexia nervosa, [Bissada et al. \(2008\)](#) found significant increases in weight and reductions in obsessive symptoms among those treated with olanzapine. Similarly, in an 8-week study of 23 outpatient women with anorexia nervosa, end-of-treatment body mass index was greater in women receiving olanzapine as compared with placebo. Psychological symptoms improved equally in both groups

([Attia et al. 2011](#)). However, a trial of olanzapine versus placebo in 20 adolescent girls with anorexia found no difference in median body weight from baseline at either week 5 or week 10. The two groups showed similar improvements in eating attitudes, psychological functioning, and resting energy expenditure ([Kafantaris et al. 2011](#)). A planned fourth clinical trial of adolescent girls was discontinued owing to inability to adequately recruit subjects, primarily because potential subjects did not meet study criteria (71% of those screened) and eligible subjects declined participation due to concerns about medication use (74% of those eligible) ([Norris et al. 2010](#)).

Given that weight gain is a prominent side effect of olanzapine, studies have begun to examine the mechanisms underlying this effect and the possibility that olanzapine might be useful as a weight-gain agent. In a double-blind, placebo-controlled trial investigating whether olanzapine might induce weight gain through modulation of ghrelin and leptin (hormones associated with satiety), patients with anorexia received olanzapine concurrently with CBT, with levels of ghrelin and leptin assessed over 3 months. Although both the olanzapine patients and the placebo patients gained weight, there was no statistical difference between the groups in amount of weight gained or in leptin or ghrelin levels, which remained unchanged over the course of the study ([Brambilla et al. 2007](#)).

The role of olanzapine as an augmentation to psychotherapy in anorexia nervosa is limited at best. The majority of studies using the most rigorous methods did not find psychological improvement for patients after olanzapine augmentation. However, in patients for whom timely weight gain is medically imperative, there may be a limited role for olanzapine. Trials have been small, with

mixed results; further research is required to clarify the potential benefits and risks for patients.

## **Posttraumatic Stress Disorder**

Posttraumatic stress disorder (PTSD) is characterized by disproportionate and disturbing symptoms of fear persisting for longer than 1 month after a severe trauma. For some patients, psychosis can occur, leading to intense feelings of horror and helplessness. This phenomenon led investigators to consider a potential role for olanzapine in a broader treatment plan for PTSD patients.

A limited number of small studies have examined olanzapine's potential utility in the treatment of PTSD. In a double-blind, placebo-controlled augmentation trial of olanzapine in 19 patients with PTSD who were minimally responsive to 12 weeks of SSRI treatment, olanzapine produced limited symptomatic improvements compared with placebo on measures of PTSD, depression, and sleep ([Stein et al. 2002](#)). However, overall clinical improvement with olanzapine was no different from that with placebo, and patients receiving olanzapine had an average weight gain of 13 pounds. In a 6-week open-trial comparison of olanzapine versus fluphenazine as monotherapy in male patients with combat-related PTSD and psychosis, olanzapine was significantly more efficacious than fluphenazine in reducing symptoms on the PANSS (negative, general, psychopathology subscale, supplementary items), Watson's PTSD subscales (avoidance, increased arousal), and a variety of global impression scales (Clinical Global Impression Severity Scale [CGI-S], Clinical Global Impression Improvement Scale [CGI-I], Patient Global Impression Improvement Scale [PGI-I]) when evaluated at 3 and 6 weeks. The two medications produced

similar improvements on PANSS positive and Watson's trauma re-experiencing subscale scores. An additional 3 weeks of treatment did not increase the efficacy of either drug ([Pivac et al. 2004](#)). In a small double-blind, randomized, placebo-controlled trial in patients with non-combat-related PTSD, olanzapine-treated patients demonstrated significantly greater improvement on the Clinician Administered PTSD Scale over 8 weeks of treatment compared with those treated with placebo ([Carey et al. 2012](#)).

## **Obsessive-Compulsive Disorder**

Obsessive-compulsive disorder (OCD) is characterized by recurrent, unwanted, and anxiety-inducing thoughts and repetitive behaviors that a person feels driven to perform in response to those thoughts. At times, obsessive thoughts can become sufficiently divorced from reality that they resemble or overlap with psychosis.

A few double-blind, placebo-controlled clinical trials have examined olanzapine's potential efficacy in augmentation of traditional SSRI treatment in OCD patients. The first such trial enrolled 26 patients who had not responded to traditional SSRI therapy. Patients received olanzapine or placebo augmentation for 6 weeks, with biweekly assessment on the Yale-Brown Obsessive Compulsive Scale (Y-BOCS). Six (46%) of the 13 olanzapine-treated patients showed symptom response (defined as a 25% or greater reduction on Y-BOCS scores), compared with none of the placebo-treated patients ([Bystritsky et al. 2004](#)). In the second trial, partial responders or nonresponders to fluoxetine received an additional 6 weeks of either olanzapine or placebo augmentation. Both groups improved, but there were no differences between groups in

the extent or timing of improvement as measured by Y-BOCS scores ([Shapira et al. 2004](#)). Findings of more recent studies provide further confirmation that olanzapine is effective in only a limited set of OCD patients, such as those with primarily hoarding or symmetry-based symptoms; the data do not support the drug's first-line use in OCD overall ([Matsunaga et al. 2009](#)). Given the mixed results and small sample sizes of the existing studies, it is clear that further research is needed to establish the benefit, if any, of olanzapine augmentation in the treatment of OCD patients.

---

## Side Effects and Toxicology

---

### Neurological and Extrapyrarnidal Adverse Effects

Adverse effects of olanzapine reported in clinical use are consistent with findings in preclinical studies, which predicted few neurological effects. In Phase II and III clinical trials, olanzapine-treated patients generally showed an improvement in EPS from baseline, reflecting the fact that most of the subjects had previously taken first-generation antipsychotics. In a large multinational comparison study ([Tollefson et al. 1997](#)), olanzapine produced fewer treatment-emergent neurological adverse effects than haloperidol, including parkinsonism (14% vs. 38%) and akathisia (12% vs. 40%). In a comprehensive meta-analysis, the relative risk (RR) of EPS for olanzapine was 0.39 compared with haloperidol ([Leucht et al. 2009](#)).

Antiparkinsonian medication is sometimes required when patients are treated with olanzapine, although the need for such medication may be lower with olanzapine than with antipsychotics having greater potency at the dopamine D<sub>2</sub> receptor. In one study ([Volavka et al. 2002](#)), antiparkinsonian agents were prescribed to 13% of both clozapine-treated subjects and olanzapine-treated subjects, compared with 32% of risperidone-treated patients. In a meta-analysis of randomized controlled trials, [Komossa et al. \(2010\)](#) found that olanzapine incurred a modestly higher risk of EPS (as measured by use of antiparkinsonian medication) compared with quetiapine (RR=2.05) but a lower EPS risk compared with risperidone (RR=0.78) and ziprasidone (RR=0.70).

Evidence now exists for phenotypic variation in the risk of EPS among olanzapine-treated patients. A meta-analysis of 4,831 subjects compared the incidence of olanzapine-induced EPS in schizophrenia versus bipolar patients. Parkinsonism was significantly higher among schizophrenia patients (13.9% vs. 3.1%), and this difference remained significant after adjustment for gender. There were no differences between groups on measures of akathisia or use of antiparkinsonian medication ([Motesafi et al. 2012](#)).

The reduction of EPS is predictive of decreased risk of tardive dyskinesia, the most problematic of the common adverse effects of classic antipsychotics. The accumulated experience with second-generation antipsychotics indicates that tardive dyskinesia is 10- to 15-fold less common with these agents than with conventional agents, with an annual rate of 0.52% for olanzapine-treated patients compared with 7.45% for haloperidol-treated patients, based on pooled data from long-term comparison trials ([Beasley et al. 1999](#)). [Miller et al. \(2008\)](#) examined data from the

previously described CATIE study. After exclusion of subjects who met criteria for tardive dyskinesia at baseline, there was no difference in incidence of tardive dyskinesia over 1 year between patients treated with olanzapine and patients treated with any other antipsychotic (perphenazine, quetiapine, risperidone, or ziprasidone).

## Weight Gain and Other Metabolic Effects

Weight gain and associated dyslipidemia are among the most significant major adverse effects found during treatment with olanzapine. Weight gain is a serious concern, because persons with schizophrenia are more likely than the general population to be obese, and weight gain may contribute to nonadherence to antipsychotic treatment, leading to increased risk for relapse. With the reduced risk of neurological side effects attached to second-generation antipsychotic agents, metabolic effects have emerged as a major risk for patients and a focus of consideration for clinicians.

The relative degree of weight gain associated with first- and second-generation antipsychotics was studied in a comprehensive meta-analysis by [Allison et al. \(1999\)](#). Estimates of weight change associated with standardized dosages over 10 weeks were calculated from published data on 81 studies. Clozapine produced the greatest weight gain (4.45 kg), followed by olanzapine (4.15 kg). By comparison, risperidone was associated with a gain of 2.1 kg and haloperidol was associated with a gain of 1.08 kg, whereas patients lost 0.74 kg while taking placebo. In long-term treatment, 30%–50% of patients gain more than 7% of

body weight, with low pretreatment weight and good clinical response associated with more weight gain ([Russell and Mackell 2001](#)). In a large database of British patients, use of olanzapine conferred a fivefold increase in the risk of dyslipidemia over an untreated control condition and a threefold increase over conventional antipsychotics, whereas risperidone did not increase the risk ([Koro et al. 2002b](#)).

The risk for metabolic dysfunction appears to be present even before patients receive antipsychotics, and risk is further compounded by antipsychotic medication use. In a sample of 404 patients with first-episode psychosis enrolled in community health centers, patients with no previous exposure to antipsychotics had lower levels of non-high-density lipoprotein (HDL) cholesterol but were more likely to carry diagnoses of obesity and hypertension compared with patients with any lifetime exposure to antipsychotic medication (average exposure = 47.3 days) ([Correll et al. 2014](#)). Furthermore, longer duration of antipsychotic treatment was associated with greater abnormalities in triglycerides and cholesterol (both HDL and non-HDL) and lower systolic blood pressure. In this study, which allowed treatment with any antipsychotic or no medication, patients receiving olanzapine had a significantly increased risk for elevated triglycerides, insulin, and homeostasis model assessment for insulin resistance (HOMA-IR) compared with patients receiving other antipsychotic medications ([Correll et al. 2014](#)).

Studies using metformin, an agent known to decrease hepatic glucose output, have tested its potential to help patients either lose weight or remain at the same weight while receiving olanzapine or other second-generation antipsychotics. In a double-blind, placebo-controlled trial

([Baptista et al. 2006](#)), patients were given 10 mg of olanzapine and randomly assigned to receive either metformin or placebo for 14 weeks. No differences between groups were seen in body mass index or waist circumference. There was a modest improvement in overall glucose levels and in HOMA-IR, but no change was seen in lipid levels. A follow-up study conducted by the same group ([Baptista et al. 2007](#)) demonstrated similar results, although in the second study, small differences in weight gain between the groups were found, with the metformin group losing an average of 1.5 kg and showing decreased leptin levels, whereas the placebo group maintained a consistent weight.

Investigators from the Use of Metformin in the Treatment of Antipsychotic-Induced Weight Gain in Schizophrenia (METS) Study randomly assigned 148 clinically stable overweight outpatients with schizophrenia or schizoaffective disorder to up to 2,000 mg of metformin or placebo daily ([Jarskog et al. 2013](#)). Patients were taking either one or two of any of the FDA-approved antipsychotic medications. All patients received weekly diet and exercise counseling. After 16 weeks, metformin-treated patients had lost significantly more weight than placebo-treated patients (6.6 lbs. vs. 2.2 lbs.). The metformin group also showed significant reductions in triglyceride levels ( $-7.0$  mg/dL vs.  $+13.2$  mg/dL) as well as modest reductions in hemoglobin A1c, a measure of elevated blood glucose ( $-0.06\%$  vs.  $+0.011\%$ ), with a time-by-treatment interaction, suggesting that the benefits of metformin increase with time. There were no significant differences in fasting glucose or insulin levels ([Jarskog et al. 2013](#)).

In a double-blind, placebo-controlled trial in adolescents who had gained weight after 1 year of treatment with a

second-generation antipsychotic (olanzapine, risperidone, or quetiapine), the addition of metformin resulted in statistical reductions in waist circumference and body mass index and stabilization of weight gain ([Klein et al. 2006](#)). HOMA-IR scores were significantly decreased, and the number of subjects requiring referral for a glucose tolerance test was reduced, among the subjects who received metformin.

Interestingly, a recent small study of first-episode schizophrenia patients started on olanzapine found that daily supplementation with melatonin attenuated increases in weight and abdominal obesity as compared with olanzapine and placebo, and additionally improved scores on the PANSS. There was also a trend for attenuation of hypertriglyceridemia ([Modabbernia et al. 2014](#)).

Weight gain is an even greater concern in the treatment of children and adolescents, who may be exposed to medication for a longer time than adults. In a study evaluating weight gain among hospitalized adolescents after 12 weeks of treatment with olanzapine ( $n=21$ ), risperidone ( $n=21$ ), or haloperidol ( $n=8$ ), patients in the olanzapine group gained an average of  $7.2\pm6.3$  kg, approximately twice the amount gained in the risperidone group ( $3.9\pm4.8$  kg) and more than 6 times the amount gained in the haloperidol group ( $1.1\pm3.3$  kg) ([Ratzoni et al. 2002](#)). In a double-blind multisite trial comparing first- and second-generation antipsychotic medications among children and adolescents, the olanzapine arm was discontinued because of weight gain without evidence of improved efficacy over risperidone or molindone ([Sikich et al. 2008](#)). A further study of olanzapine in adolescents demonstrated a statistically significant difference in symptom improvement ratings for olanzapine over placebo.

As in previous studies, significantly more weight gain occurred in the adolescents on olanzapine ([Kryzhanovskaya et al. 2009b](#)).

Changes in weight, lipids, and insulin metabolism raise serious concerns for diabetes and related complications. Cases reported to the FDA Drug Surveillance System and published cases of olanzapine-associated diabetes and hyperglycemia were reviewed by [Koller and Doraiswamy \(2002\)](#). Two hundred eighty-nine cases were identified, of which 225 (78%) involved new-onset diabetes and 100 (35%) involved ketosis or acidosis; in 23 (8%) cases, the patient died. Most cases developed within 6 months of initiation of olanzapine therapy. Many cases occurred during the first month of therapy, indicating that weight gain alone did not mediate the occurrence of diabetes-related problems. On the basis of the temporal relation between the appearance of metabolic changes and the introduction and withdrawal of olanzapine, the young age of patients affected, and the number of reports, the authors concluded that the data suggested that olanzapine was causally related to the development or worsening of diabetes. A similar conclusion about clozapine and diabetes had been reported previously ([Koller et al. 2001](#)). Because case studies and reports by clinicians to regulatory agencies may reflect reporting bias, controlled studies comparing the development of metabolic disorders are needed to clarify whether these are related to the underlying psychosis, causally related to drug treatment in general, or specifically related to individual agents.

Studies using large health system databases have linked antipsychotic treatment with subsequent diagnoses of diabetes or use of hypoglycemic agents. These studies show an increased risk of development of type 2 diabetes among

individuals using olanzapine or clozapine relative to those using risperidone or typical antipsychotics or compared with matched untreated persons ([Gianfrancesco et al. 2002](#); [Koro et al. 2002a](#); [Sernyak et al. 2002](#)).

In addition to olanzapine's association with weight gain and type 2 diabetes, it has also been linked to diabetic ketoacidosis (DKA), a condition more often associated with type 1 than type 2 diabetes mellitus. Reports of this connection first appeared in the literature in 1999 ([Gatta et al. 1999](#); [Goldstein et al. 1999](#); [Lindenmayer and Patel 1999](#)). In a review of California Medicaid data on cases of risperidone- and olanzapine-associated DKA, [Ramaswamy et al. \(2007\)](#) found a higher incidence of DKA with olanzapine treatment than with risperidone treatment and noted that the risk increased with duration of treatment with olanzapine. By contrast, a multicenter retrospective cohort study using administrative health data (encompassing the records of 725,489 patients) from Canada and the United Kingdom ([Lipscombe et al. 2014](#)) found no increased risk of hyperglycemic emergency associated with initiation of olanzapine versus risperidone.

## Other Side Effects

Among other side effects reported with olanzapine, sedation is frequent at the start of therapy but diminishes as patients develop tolerance for this side effect. In long-term treatment, the incidence of sedation is about 15%, similar to that of haloperidol. Prolactin elevations observed during olanzapine treatment occur early in the course of treatment, and levels are much lower than those seen with risperidone or typical antipsychotics. Leukopenia is rare

and occurs at a rate similar to that seen with other first- and second-generation antipsychotics, but olanzapine does not cause agranulocytosis, even in patients who developed this effect while taking clozapine. In animal toxicology studies and in clinical trials of olanzapine, no QTc prolongation was observed, and other cardiovascular effects are rarely of clinical importance ([Cadario 2000](#)).

## Safety in Overdose

Reviews of case series and reports of olanzapine toxicity in adults describe predominantly circulatory and central nervous system effects, including coma, psychomotor agitation, hypertension and hypotension, tachycardia and bradycardia, hyperthermia and hypothermia, miosis and mydriasis, and QTC prolongation (QTC prolongation only with >1,040-mg ingestion and in mixed overdoses) ([Ciszowski et al. 2011](#); [Tan et al. 2009](#)). Olanzapine overdose was rarely fatal in the aforementioned case reports, and a systematic study of second-generation antipsychotic overdose found that of 422 olanzapine overdoses, there were no fatalities and 14% required ventilation ([Berling et al. 2016](#)). There are very few data describing olanzapine overdose in children. Available case report data are consistent with adult presentations of EPS and elevated prolactin levels ([Tanoshima et al. 2013](#)) and circulatory and neurological symptoms ([McAllister et al. 2012](#); [Singh et al. 2012](#); [Theisen et al. 2005](#)).

## Use in Pregnancy

Exposure to second-generation antipsychotics was associated with gestational diabetes in a Swedish birth cohort study ([Bodén et al. 2012](#)). The risk was similar for medications known to have severe anabolic effects (olanzapine and clozapine) and other antipsychotic medications. Fetuses exposed to antipsychotic medication in utero were more likely than those not exposed to be born small for gestational age, but this association was not robust to adjustment for maternal factors. Because of the difficulty in studying medication use during pregnancy, data on antipsychotic use during pregnancy are extremely sparse. No specific fetal abnormalities have been reported with olanzapine, although there is some evidence suggesting an association between antipsychotic use in pregnancy and neonatal respiratory distress and withdrawal symptoms ([Kulkarni et al. 2015](#)). Further research is needed to aid clinicians in maximizing infant and maternal well-being.

---

## Drug-Drug Interactions

---

Olanzapine is metabolized primarily via glucuronidation and via oxidation by CYP1A2 (see section “Pharmacokinetics and Disposition” earlier in this chapter). Other drugs that affect the activity of these metabolic pathways would therefore be expected to affect olanzapine pharmacokinetics. Indeed, drugs that inhibit CYP1A2 activity have been shown to decrease olanzapine clearance, thereby increasing olanzapine plasma concentrations.

Fluvoxamine, a known inhibitor of CYP1A2, has been shown to inhibit olanzapine metabolism in several studies.

In an 11-day study of 10 healthy male smokers, coadministration of fluvoxamine (50–100 mg/day) with olanzapine (2.5–7.5 mg/day for 8 days [beginning on day 4]) resulted in an 84% increase in olanzapine peak serum concentrations ( $C_{\max}$ ) and a 119% increase in  $AUC_{0-24}$  compared with placebo coadministered with olanzapine. No change in half-life was observed in either olanzapine or 4'-*N*-desmethylolanzapine, suggesting that fluvoxamine inhibited olanzapine's first-pass metabolism ([Maenpaa et al. 1997](#)).

Fluoxetine and imipramine, although not known to be significant inhibitors of CYP1A2, when coadministered with olanzapine have been associated with small but statistically significant changes in olanzapine pharmacokinetics. Coadministration of fluoxetine with olanzapine resulted in a 15% decrease in olanzapine clearance and an 18% increase in  $C_{\max}$ , with no significant difference in olanzapine half-life ([Callaghan et al. 1999](#)). Coadministration of imipramine with olanzapine resulted in an approximately 14% increase in olanzapine  $C_{\max}$  and a non-statistically significant increase in olanzapine AUC of 19% ([Callaghan et al. 1997](#)).

Inducers of the CYP1A2 enzyme increase olanzapine clearance, thereby decreasing olanzapine systemic exposure. Carbamazepine, an inducer of several CYP enzymes (including 1A2), affects olanzapine disposition. A study in healthy volunteers reported that a single 10-mg dose of olanzapine taken after 2 weeks of pretreatment with carbamazepine (200 mg twice daily) had significantly higher clearance and apparent volume of distribution—but significantly lower  $C_{\max}$ , AUC, and half-life—compared with a single 10-mg dose taken before carbamazepine pretreatment ([Lucas et al. 1998](#)).

Smoking, also known to induce CYP1A2, can affect olanzapine disposition. A study comparing 19 male smokers with 30 male nonsmokers found that olanzapine clearance in smokers was 23% higher than that in nonsmokers ([Callaghan et al. 1999](#)). A population pharmacokinetic analysis of 910 patients receiving olanzapine found that clearance among nonsmokers was 37% lower in men and 48% lower in women than it was in the corresponding group of smokers ([Patel et al. 1996](#)). A smaller analysis of healthy volunteers also found higher drug clearances among smokers ([Patel et al. 1995](#)). The polycyclic aromatic hydrocarbons in cigarette smoke are responsible for inducing the aryl hydrocarbon hydroxylases, thereby leading to enzymatic induction ([Desai et al. 2001](#)). For this reason, dosage adjustments may be needed when a patient who smokes is placed in a smoke-free inpatient unit, even if adequate nicotine replacement is provided. Conversely, when there is a sudden increase in cigarette consumption (often associated with stress or impending relapse), a dosage increase may be needed to prevent an abrupt worsening of symptoms.

In vitro studies suggest that olanzapine does not significantly inhibit the activity of CYP 1A2, 3A, 2D6, 2C9, or 2C19 ([Ring et al. 1996a](#)). In vivo studies suggest that olanzapine does not affect the disposition of aminophylline ([Macias et al. 1998](#)), diazepam, alcohol, imipramine ([Callaghan et al. 1997](#)), warfarin, biperiden, or lithium ([Callaghan et al. 1999](#); [Demolle et al. 1995](#)).

---

## Conclusion

---

From review of the research focused on olanzapine, it is clear that this compound, which has been approved for use in the United States since 1997, has wide utility and some distinct advantages compared with traditional antipsychotics. In addition to its positive effects on a broad group of symptoms in schizophrenia, olanzapine is approved for the treatment of mania, both acute and long term, in bipolar disorder. Recent research has shown that olanzapine may be beneficial for disorders beyond psychosis (e.g., borderline personality disorder, anorexia nervosa, PTSD, OCD). The extension of olanzapine's uses is in many ways made possible by its low rate of movement disorders. Olanzapine's low risk of dystonia, parkinsonism, and tardive dyskinesia has led to its greater acceptability in chronic schizophrenia and has encouraged clinicians to prescribe it for other conditions, although concerns about metabolic side effects limit the drug's overall utility.

As noted in the earlier section "Side Effects and Toxicology," olanzapine is not free of adverse effects. Weight gain and metabolic disturbances are of significant concern and are the focus of intense research in both pathophysiology and prevention/treatment. Because of these concerns, the FDA does not recommend olanzapine as a first-line agent in young people.

In addition to providing better treatment for schizophrenia and other disorders, olanzapine promotes actions in the brain that have revealed new directions for research on the pathophysiological mechanisms underlying psychiatric disease. As noted previously, investigation of olanzapine's effects on glutamate, neurotensin, neuregulin, and other neurotransmitters may improve our understanding of the pathophysiology of these diseases and open new avenues of treatment.

## CHAPTER 27

# Quetiapine

Peter F. Buckley, M.D.

Adriana E. Foster, M.D.

Matthew Byerly, M.D.

---

### History and Discovery

Quetiapine is a second-generation antipsychotic (SGA) developed and subsequently marketed by AstraZeneca. In preclinical trials, quetiapine showed the features associated with antipsychotic efficacy, as well as a low rate of motor effects ([Goldstein 1999](#); [Nemeroff et al. 2002](#)). Quetiapine was approved in 1997 by the U.S. Food and Drug Administration (FDA) for the treatment of schizophrenia; it was subsequently approved in Europe and in other countries worldwide. Additional approvals and indications for quetiapine's use in bipolar disorder, as well as approval of an extended-release formulation of quetiapine, have followed ([Möller et al. 2007](#); [Peuskens et al. 2007](#)). The extended-release formulation has an additional indication as adjunctive treatment for major depression in patients who show inadequate response to antidepressants alone.

---

### Structure-Activity Relations

Quetiapine is an SGA of the dibenzothiazepine class ([Figure 27-1](#)). Its complex neuropharmacology includes a relatively low binding profile for dopamine type 2 ( $D_2$ ) receptors ([Kapur et al. 2000](#)). Indeed, considering the idea that an antipsychotic needs to occupy 60% or more of  $D_2$  receptors in order to be clinically efficacious ([Kapur et al. 2000](#)), quetiapine's low  $D_2$  binding—typically, approximately 30%—is noteworthy.

**FIGURE 27-1.** Chemical structure of quetiapine

Source. PubChem Compound Database, National Center for Biotechnology Information. Available at: <http://www.ncbi.nlm.nih.gov/pccompound>.

In attempting to reconcile this apparently subtherapeutic  $D_2$  receptor antagonism with the well-recorded efficacy of quetiapine as an antipsychotic, [Kapur et al. \(2000\)](#) proposed an elegant *kiss and run hypothesis* to explain quetiapine's mechanisms of action. In a series of studies, they found that when  $D_2$  receptor occupancy with quetiapine was measured with positron emission tomography at shorter intervals (4 hours and 6 hours) than the conventional 12 hours after the last dose was taken, quetiapine did indeed show high  $D_2$  occupancy. In contrast to other antipsychotics, quetiapine demonstrated a more rapid "run-off" from  $D_2$  receptors; that is, there was rapid dissociation of the  $D_2$  receptors ([Kapur et al. 2000](#)).

Like clozapine, quetiapine has strong binding at 5-hydroxytryptamine (serotonin) type 2 ( $5-HT_2$ ) receptors. This profile contrasts with its relatively weak affinity for other subclasses of the serotonin receptor family ([Nemeroff et al. 2002](#)). Quetiapine also has strong affinity for  $\alpha_1$ -noradrenergic receptors. This antagonism may relate to its propensity to induce postural hypotension—especially during rapid dosage titration. Additionally, quetiapine has strong antagonism at histamine type 1 ( $H_1$ ) receptors. This most likely relates to its sedative effect.  $H_1$  receptor antagonism also appears to be a key contributor to weight gain during quetiapine therapy ([Kim et al. 2007](#)).

---

## Pharmacokinetics and Disposition

---

Quetiapine's absorption in the gastrointestinal tract is unaffected by food. With the tablet formulation, peak blood levels are achieved in about 2 hours, with effective plasma levels

sustained for approximately 6 hours ([DeVane and Nemeroff 2001](#)). Although this provides the basis for the usual clinical regimen of twice-daily dosing, a short-term trial comparing once-daily dosing with twice-daily dosing demonstrated that the two regimens were equivalent in terms of efficacy and tolerability ([Chengappa et al. 2003b](#)). A positron emission tomography study ([Mamo et al. 2008](#)) found comparable plasma levels and D<sub>2</sub> receptor occupancy between the immediate-release (IR) and the extended-release (XR) formulation.

Quetiapine is metabolized by cytochrome P450 (CYP) 3A4 to inactive metabolites. Coadministration with drugs that alter CYP3A4 activity is likely to result in clinically significant interactions. For example, the anticonvulsants carbamazepine and phenytoin are CYP3A4 inducers, and in their presence quetiapine dosages may need to be increased because of accelerated drug clearance ([Potkin et al. 2002a, 2002b](#); [Strakowski et al. 2002](#)). Ritonavir, erythromycin, ketoconazole, and nefazodone are potent inhibitors of CYP3A4, and their concomitant use with quetiapine requires caution.

Clinical trials ([Kahn et al. 2007](#); [Lindenmayer et al. 2008](#)) comparing the efficacy and tolerability of the XR formulation with the regular IR formulation indicated that quetiapine XR given once daily (at dosages of 400–800 mg/day) was effective for the treatment of schizophrenia and, on average, was similar in efficacy and tolerability to treatment with quetiapine IR. Quetiapine is excreted in the kidneys and is not affected by gender or smoking status. The metabolism of quetiapine is reduced by approximately 30% with advancing age ([Goldstein 1999](#)). Quetiapine is available only in tablet formulations; there are no liquid or intramuscular preparations.

---

## Indications and Efficacy

---

Quetiapine in the XR and IR formulations is FDA approved for the following indications in adults: treatment of schizophrenia; acute treatment of manic or mixed episodes associated with bipolar I disorder, both as monotherapy and as an adjunct to lithium or divalproex; acute treatment of depressive episodes associated with bipolar I or II disorder; and maintenance treatment of bipolar I disorder as an adjunct to lithium or divalproex. The XR formulation is also approved for use as an adjunct to antidepressant therapy in the treatment of major depressive disorder in adults.

In addition, quetiapine is efficacious in the treatment of schizophrenia and bipolar disorder in pediatric populations ([Barzman et al. 2006](#); [DelBello et al. 2007](#); [McConville et al. 2000](#)). The IR formulation is FDA approved for the treatment of schizophrenia in adolescents (ages 13–17 years) and the acute treatment of manic or mixed episodes associated with bipolar I disorder in children and adolescents (ages 10–17 years).

There are also reports of quetiapine's efficacy in treating anxiety disorders, obsessive-compulsive disorder (OCD), borderline personality disorder, and Parkinson's disease. These uses have not been approved by the FDA. The use of any medication (in this case quetiapine) in situations that are not FDA-approved indications is not recommended in clinical practice.

## Schizophrenia

Registration and early trials of quetiapine ([Arvanitis and Miller 1997](#); [Borison et al. 1996](#); [Copolov et al. 2000](#); [King et al. 1998](#); [Peuskens and Link 1997](#); [Small et al. 1997](#))

demonstrated that quetiapine is an efficacious antipsychotic for the treatment of schizophrenia. Short-term (6-week) trials compared quetiapine, haloperidol, and placebo using quetiapine at flexible daily dosages of  $\leq 250$  mg or  $\leq 750$  mg (Small et al. 1997) or fixed daily dosages of 75 mg, 150 mg, 300 mg, 600 mg, or 750 mg (Arvanitis and Miller 1997); the latter trial found that 300 mg/day was superior (but not statistically significantly so) to the lower and higher dosages and was the only dosage demonstrating efficacy for negative symptoms (Arvanitis and Miller 1997). These studies established a range of effective dosages for quetiapine and also suggested that dosages of  $\geq 250$  mg/day were superior to lower dosages.

Subsequent studies helped refine quetiapine dosing strategies. An 8-week fixed-dosage comparison trial of quetiapine at 600 mg/day versus haloperidol at 20 mg/day showed similar efficacy for the two drugs in patients who were partial responders to first-generation antipsychotics (FGAs) (Emsley et al. 2000). A study comparing a rapid titration strategy (beginning at 200 mg/day, increasing to 800 mg/day by day 4) with a more conventional dosing strategy (50 mg/day on day 1, increasing up to 400 mg/day by day 5) showed similar efficacy and tolerability for the two strategies (Pae et al. 2007). Growing evidence from more recent studies (Honer et al. 2012; Lindenmayer et al. 2011) discourages the use of very-high-dosage quetiapine, and data are still lacking to indicate that dosages above 300–400 mg/day are more efficacious.

Most studies comparing quetiapine with either an FGA or another SGA have reported similar efficacy for the agents in treating schizophrenia (Emsley et al. 2000; Peuskens and Link 1997; Small et al. 1997). A 4-month open-label trial of quetiapine and risperidone showed overall comparability between the two agents (Mullen et al. 2001). An 8-week comparative trial of quetiapine (with an average dosage of 525 mg/day) and risperidone (with an average dosage of 5.2 mg/day) also found the drugs similar in efficacy (Zhong et al. 2006). Quetiapine-treated patients had fewer extrapyramidal side effects (EPS), lower prolactin levels, and fewer sexual side effects. Whereas weight gain was similar in both treatment groups, quetiapine was more sedating and was more frequently associated with dry mouth than was risperidone. A 6-month study comparing quetiapine and risperidone reported better efficacy for risperidone (Potkin et al. 2006), with quetiapine associated with more polypharmacy. A 6-month double-blind comparative trial of quetiapine and olanzapine (Kinon et al. 2006) reported that quetiapine-treated patients were less likely to complete the study, although relapse rates were comparable overall in the two treatment groups. More weight gain occurred in olanzapine recipients. As yet, no studies have directly compared quetiapine with aripiprazole, iloperidone, asenapine, or lurasidone in the treatment of schizophrenia.

The most extensive comparative evaluation of quetiapine and other SGAs comes from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE). In the Phase I study, more quetiapine-treated patients than olanzapine-treated patients had discontinued treatment by 18 months (78% vs. 64%), and a similar (not statistically significant) trend was seen in comparisons of quetiapine versus risperidone, ziprasidone, or perphenazine (Lieberman et al. 2005). In the Phase II study, discontinuation rates favored clozapine and olanzapine over risperidone and quetiapine (McEvoy et al. 2006). The results from the tolerability pathways were mixed and showed similar efficacy for quetiapine versus other agents (Stroup et al. 2007). The findings relating to quetiapine's relative adverse-effects profile in this formative study are presented in the section "Side Effects and Toxicology." Another interesting analysis from the CATIE schizophrenia studies (Stroup et al. 2007) examined how those patients originally assigned to the perphenazine arm of the Phase I study fared. In this analysis, switching to quetiapine was more efficacious than switching

to any of the other agents. Many of the efficacy and tolerability differences among agents observed in the CATIE schizophrenia studies have been attributed to differential dosing profiles.

An analogous comparative trial of quetiapine, risperidone, and olanzapine was conducted with patients experiencing a first episode of psychosis—the Comparison of Atypicals in First Episode Psychosis (CAFE) study. Here, discontinuation rates were similar across drugs over the 1-year trial ([McEvoy et al. 2007](#)). Two recent studies inform the comparative efficacy and tolerability of quetiapine in adolescents with psychosis (and related conditions) ([Arango et al. 2014](#); [Pérez-Iglesias et al. 2014](#)). [Pérez-Iglesias et al. \(2014\)](#) found that quetiapine increased weight and cholesterol levels over 3 months. Similarly, [Arango et al. \(2014\)](#) found that quetiapine increased weight (less so than olanzapine, more so than risperidone) over 6 months in children and adolescents, although in this study, there was no rise in cholesterol in quetiapine-treated patients.

The use of quetiapine in patients with prodromal features of schizophrenia has not yet been studied. A small study of quetiapine in schizophrenia patients with comorbid substance abuse was inconclusive ([Brunette et al. 2009](#)).

## Mood Disorders

There is evidence that quetiapine is an effective and well-tolerated antipsychotic for treating patients with bipolar mania and bipolar depression. [Bowden et al. \(2005\)](#) demonstrated that quetiapine was superior to placebo in the treatment of mania. In this multicenter study, significantly more patients treated with quetiapine than with placebo met criteria for response (greater than 50% decrease from baseline score on the Young Mania Rating Scale) at 7, 21, and 84 days. Building on initial evidence for mood effects that was derived from observations on mood assessment items in the pivotal schizophrenia trials, the Quetiapine Experience with Safety and Tolerability (QUEST) study compared quetiapine with risperidone in a 4-month open-label, flexible-dose trial ([Mullen et al. 2001](#)). This study included patients with schizophrenia, schizoaffective disorder, bipolar disorder, and depression. At week 16, the mean dosage of quetiapine was 317 mg/day, and the mean dosage of risperidone was 4.5 mg/day. Mean improvement on the Hamilton Rating Scale for Depression was significantly greater in quetiapine recipients than in risperidone recipients.

[Calabrese et al. \(2005\)](#) and [Thase et al. \(2006\)](#) have studied quetiapine use in patients with bipolar depression. In an 8-week trial, [Calabrese et al. \(2005\)](#) compared two dosages of quetiapine (300 mg/day and 600 mg/day) with placebo. Both dosages were efficacious, with improvements observed across the full range of depressive and anxiety symptoms. Fifty-eight percent of patients met a priori criteria for treatment response. Additionally, this antidepressant effect was observed with a once-daily dosage regimen. In a subsequent similar study ([Thase et al. 2006](#)) of the same two dosages (300 mg/day and 600 mg/day), quetiapine was again compared with placebo in an 8-week trial in patients with bipolar depression. Again, both dosages of quetiapine showed efficacy across a broad range of depressive symptoms. These two studies led to FDA approval of quetiapine for treating bipolar depression.

Two large 8-week international multicenter studies—Efficacy of Monotherapy Seroquel in BipOLar DEpression (EMBOLDEN) I ([Young et al. 2010](#)) and II ([McElroy et al. 2010](#))—compared quetiapine 300 mg/day and 600 mg/day with lithium 600–1,800 mg/day and placebo (EMBOLDEN I) and with paroxetine 20 mg/day and placebo (EMBOLDEN II) in bipolar patients with a major depressive episode. In the first study ([Young et al. 2010](#)),

quetiapine at both dosages, but not lithium, led to significant improvement in symptoms of depression and anxiety. Compared with patients receiving placebo, patients treated with quetiapine 300 mg/day and 600 mg/day showed significant improvement on the Sheehan Disability Scale. In the second study ([McElroy et al. 2010](#)), quetiapine 300 mg/day and 600 mg/day, but not paroxetine 20 mg/day, led to significant improvement in depressive and anxiety symptoms. Neither lithium nor paroxetine led to significant functional improvement over placebo in these studies. In both studies, a small subgroup of patients with rapid-cycling bipolar disorder did not improve significantly from baseline with any of the drugs administered (quetiapine, lithium, or paroxetine).

In a long-term naturalistic study ([Ketter et al. 2010](#)) of quetiapine administered to 96 patients with bipolar disorder in a clinical setting, 38.5% of patients continued taking quetiapine for 328 days without the addition of other psychotropics, whereas 22.9% of patients continued taking quetiapine for 613 days with the addition of another psychotropic, most often for depression. In a small double-blind, placebo-controlled pilot study ([DelBello et al. 2009](#)) of quetiapine 300–600 mg/day in depressed adolescents with bipolar disorder, quetiapine neither differentiated from placebo nor induced significant change in symptoms from baseline to endpoint on measures of depressive, anxiety, or manic symptoms or clinical global impressions of bipolar severity. [Bourin et al. \(2014\)](#) reported superior efficacy when lithium was added to quetiapine XR, and this combination was well tolerated.

[Dorée et al. \(2007\)](#) reported that in a pilot study ( $n=20$ ), quetiapine was an efficacious augmenting agent for antidepressant treatment in major depression. [Anderson et al. \(2009\)](#) also reported on quetiapine's efficacy as an adjunctive treatment for patients with refractory depression. Quetiapine XR monotherapy at a mean daily dosage of 162.2 mg was shown to decrease symptoms of major depression at 8 weeks versus placebo ([Bortnick et al. 2011](#)). [Cutler et al. \(2009\)](#) reported that quetiapine XR 300 mg/day led to significantly higher rates of response and remission versus placebo in major depression, whereas quetiapine XR 150 mg/day had a significant effect only on response versus placebo. Quetiapine at dosages of 150–300 mg/day is now approved by the FDA as an adjunct to antidepressant treatment for a major depressive episode. In one of the studies leading to FDA approval of quetiapine XR for this indication, [El-Khalili et al. \(2010\)](#) demonstrated that quetiapine XR at 300 mg/day led to significant improvement in symptoms of depression from the first week of treatment when compared with placebo. In a review of registration studies for the major depression indication, [McIntyre et al. \(2009\)](#) concluded that quetiapine XR provides rapid and sustained relief of major depressive symptoms. [Weisler et al. \(2012\)](#) also reported substantial improvement in depressive symptoms in two 6-week clinical trials of quetiapine XR. Remission at 6 weeks was achieved by 23.5% of patients taking 150 mg/day and by 28.8% of patients taking 300 mg/day of quetiapine. [Lin et al. \(2014\)](#) used a national insurance database from Taiwan to compare in a mirror image design the effect of augmentation of antidepressant therapy over 1 year in patients with major depressive disorder. Quetiapine, olanzapine, and aripiprazole augmentations were each effective in reducing health care utilization. [Masi et al. \(2015\)](#) reported improvement from and tolerability of quetiapine in a small open-label study comparing quetiapine and risperidone in adolescents with bipolar disorder and comorbid conduct disorder.

## Anxiety Disorders

The sedative/calming effect of quetiapine was well described in a variety of product registration trials ([Chengappa et al. 2003a](#); [Weiden et al. 2006](#)), and studies in bipolar I disorder and bipolar depression ([Calabrese et al. 2005](#); [Hirschfeld et al. 2006](#); [Thase et al. 2006](#)) demonstrated improvements in anxiety symptoms with quetiapine.

In a small 8-week study ([Vaishnavi et al. 2007](#)) of social phobia treatment, there was no significant difference in Brief Social Phobia Scale scores between the quetiapine and placebo groups, although people who took quetiapine did show a robust response as measured by Clinical Global Impression—Improvement Scale (CGI-I) scores.

Two small studies of quetiapine augmentation in patients with generalized anxiety disorder (GAD) who had not responded to antidepressant therapy ([Katzman et al. 2008](#); [Simon et al. 2008](#)) yielded contradictory results. A large double-blind, randomized, placebo-controlled study of monotherapy for GAD ([Bandelow et al. 2010](#)) compared quetiapine XR 50 mg/day or 150 mg/day, paroxetine 20 mg/day, and placebo. Significant separation from placebo on the primary outcome variable (mean reduction in Hamilton Anxiety Scale (Ham-A) total score) was seen for quetiapine XR 50 mg/day and 150 mg/day as early as 4 days into treatment, but not for paroxetine. After 8 weeks of treatment, both quetiapine 150 mg/day and paroxetine 20 mg/day had higher anxiety remission rates (Ham-A score  $\leq 7$ ) compared with placebo. Weight gain greater than or equal to 7% of body weight was noted in a higher percentage of patients treated with quetiapine than of those taking placebo. In a parallel-group, double-blind, placebo-controlled study by [Katzman et al. \(2011\)](#), 432 patients with GAD were randomly assigned to continue treatment long term with quetiapine XR (50 mg/day, 150 mg/day, or 300 mg/day) or to switch to placebo after an open-label run-in and stabilization period. During the randomized treatment period (from the point of random assignment to the end of the study), quetiapine XR significantly increased the time to occurrence of an anxiety event and decreased anxiety symptoms compared with placebo.

An analysis of the tolerability of quetiapine in patients with various disorders showed that patients with GAD, bipolar depression, or refractory major depression had significantly higher rates of discontinuation due to adverse effects versus placebo than did patients with schizophrenia or mania when treated with quetiapine XR dosages of  $\geq 300$  mg/day ([Wang et al. 2011](#)). In a systematic review and meta-analysis of all available trials of SGA medications, quetiapine was observed to have the most robust effect on anxiety symptoms ([LaLonde and Van Lieshout 2011](#)). The antianxiety effects of quetiapine were observed at lower dosages (typically 150 mg/day) than those used in schizophrenia studies, and the effects included overall improvement as well as remission. However, quetiapine was also associated with weight gain and high rates of medication discontinuation in these studies of anxiety disorder ([LaLonde and Van Lieshout 2011](#)). In three 8-week studies of quetiapine XR, [Stein et al. \(2011\)](#) reported rates of study discontinuation due to side effects of 13%, 16%, and 24% for quetiapine dosages of 50 mg/day, 150 mg/day, and 300 mg/day, respectively. In an 8-week placebo-controlled comparative trial of quetiapine XR and escitalopram, comparable improvements in anxiety symptoms, occurring early in the study, were observed with quetiapine and escitalopram ([Merideth et al. 2012](#)). In a more “real-world” population of patients with bipolar depression with substantial comorbidities (especially GAD), quetiapine XR showed no advantages over placebo in an 8-week trial ([Gao et al. 2014](#)).

At present, the FDA has not approved quetiapine for use in any anxiety disorders.

## Other Disorders

Several small studies of quetiapine augmentation (at dosages up to 400 mg/day) of SSRI pharmacotherapy in refractory OCD yielded contradictory results ([Atmaca et al. 2002](#); [Carey et al. 2005](#); [Fineberg et al. 2005](#)); although improvement in Yale-Brown Obsessive Compulsive Scale (Y-BOCS) scores was noted in patients treated with quetiapine, the response to quetiapine did not differentiate from placebo. Quetiapine's efficacy as an augmenting agent with antidepressants in treatment-resistant OCD was recently reviewed in a meta-analysis of five double-blind randomized controlled trials (RCTs) ([Komossa et al. 2010](#)). Adjunctive quetiapine was not superior to placebo in reducing Y-BOCS scores by 25% (the criterion for response in these studies), but it did reduce the Y-BOCS score significantly by the endpoint compared with placebo. A small case series also showed that adjunctive quetiapine response may be enduring ([Dell'Osso et al. 2006](#)). [Veale et al. \(2014\)](#) conducted a meta-analysis of SGAs in OCD. In contrast to benefits seen with risperidone or aripiprazole, there was no effect seen with augmentation with either quetiapine or olanzapine.

Quetiapine has been studied in the treatment of posttraumatic stress disorder ([Ahearn et al. 2006](#); [Byers et al. 2010](#); [Hamner et al. 2003](#); [Kozaric-Kovacic and Pivac 2007](#); [Sokolski et al. 2003](#); [Stathis et al. 2005](#)). All but one of the studies ([Stathis et al. 2005](#)) involved quetiapine being administered to veterans as an adjunctive agent added to selective serotonin reuptake inhibitors (SSRIs), other antidepressants, sedative-anxiolytics, or anticonvulsants. All were open-label studies, and with the exception of a retrospective chart review comparing quetiapine with the  $\alpha_1$  receptor antagonist prazosin ([Byers et al. 2010](#)), none had a comparison group. The average quetiapine dosage used in these studies was 100–335 mg/day administered for 6–8 weeks. Quetiapine decreased symptoms of avoidance, hyperarousal, and recollection in the populations studied.

## Other Conditions and Patient Populations

Quetiapine has also been used in elderly populations. In a 1-year open-label trial of quetiapine treatment in 151 elderly patients (mean age 76.8 years) with psychotic disorders ([McManus et al. 1999](#)), 52% of patients showed symptom improvement (as measured by a 20% or greater decline in Brief Psychiatric Rating Scale total score). Seventy percent of patients had some organic condition, predominantly Alzheimer's disease, with the remaining patients having a diagnosis of schizophrenia, schizoaffective disorder, or delusional disorder. Quetiapine was well tolerated at a mean dosage of 100 mg/day. A 10-week study comparing two dosages of quetiapine (100 mg/day and 200 mg/day) with placebo in nursing home residents with dementia and agitation ([Zhong et al. 2007](#)) reported that only the 200 mg/day quetiapine dosage was efficacious in treating agitation. Quetiapine (100 mg/day) was also compared with risperidone (1.0 mg/day), olanzapine (5.5 mg/day), and placebo over 36 weeks in the CATIE Alzheimer's disease study ([Schneider et al. 2006](#)). Overall, no effect on the Alzheimer's Disease Cooperative Study-Clinical Global Impression of Change Scale was seen with any of the agents, and there were no differences between agents in time to discontinuation.

In contrast to the encouraging findings from open-label studies of quetiapine for Parkinson's-associated psychosis, four of five later double-blind RCTs ([Kurlan et al. 2007](#); [Ondo et al. 2005](#); [Rabey et al. 2007](#); [Shotbolt et al. 2009](#)) found no benefit for quetiapine in this population. The single positive RCT ([Fernandez et al. 2009](#)) was small ( $N=16$ ) and excluded patients with delusions, which appear to be more difficult to treat than hallucinations in Parkinson's disease ([Shotbolt et al. 2010](#)).

Agitation is a core aspect of several conditions. [Currier et al. \(2006\)](#) reported an interesting study of quetiapine in agitated patients in the emergency department. Here, Currier and colleagues reported that quetiapine could be used as an acute antiagitation agent if the dosage titration is judicious. Postural hypotension was observed in this study. Other studies of quetiapine and agitation report benefits in treating hostility both in adults with schizophrenia ([Chengappa et al. 2003a](#)) or bipolar disorder ([Buckley et al. 2007](#)) and in children with hostile behaviors ([Barzman et al. 2006](#); [Findling et al. 2007](#)).

[Black et al. \(2014\)](#) examined low-dosage quetiapine (150 mg/day) and moderate-dosage quetiapine (300 mg/day) versus placebo in an 8-week, double-blind trial of inpatients with borderline personality disorder. Both dosages of quetiapine were effective across a range of symptoms in these patients, although there were more side effects with moderate-dosage quetiapine.

## Side Effects and Toxicology

To illustrate the profile of adverse effects typically seen with quetiapine, we have tabulated the results from an 8-week RCT ([Zhong et al. 2006](#)) ([Table 27-1](#)) in which quetiapine was compared with risperidone. Overall, quetiapine was well tolerated, with only 6% of patients discontinuing treatment because of adverse effects.

**TABLE 27-1. Comparative side-effect profile of quetiapine versus risperidone: adverse effects present in  $\geq 5\%$  of patients in an 8-week study**

Adverse effect	Quetiapine ( <i>n</i> =338; median dosage=525 mg/day)	Risperidone ( <i>n</i> =334; median dosage=5.2 mg/day)	<i>P</i> value <sup>a</sup>
	<i>n</i> (%)	<i>n</i> (%)	
Somnolence	89 (26.3)	66 (19.7)	0.044
Headache	51 (15.1)	56 (16.7)	0.599
Weight gain	48 (14.2)	45 (13.4)	0.824
Dizziness	48 (14.2)	32 (9.6)	0.0737
Dry mouth	41 (12.1)	17 (5.1)	<0.01
Dyspepsia	22 (6.5)	26 (7.8)	0.552
Nausea	21 (6.2)	22 (6.6)	0.876
Pain	21 (6.2)	24 (7.2)	0.536
Asthenia	17 (5.0)	14 (4.2)	0.714
Agitation	17 (5.0)	10 (3.0)	0.238
Pharyngitis	15 (4.4)	24 (7.2)	0.140
Akathisia	13 (3.8)	28 (8.4)	0.016
Vomiting	13 (3.8)	18 (5.4)	0.364
Dystonia	1 (0.3)	18 (5.4)	<0.001

<sup>a</sup>Fisher exact test, unadjusted.

Source. Adapted from [Zhong et al. 2006](#).

Overall, the adverse-effect profile of the XR formulation of quetiapine is similar to that of the IR formulation.

## Somnolence, Sedation, and Dizziness

Somnolence is a common side effect of quetiapine that most likely relates to its antihistaminergic activity. Although somnolence occurs early in treatment and generally decreases over time, it may persist in some patients. It may also cause patients to stop taking their medication, because sedation is generally a poorly tolerated side effect. In the bipolar depression study by [Calabrese et al. \(2005\)](#), somnolence was observed in 24% of patients taking quetiapine at a dosage of 300 mg/day and in 27% of patients taking 600 mg/day. In the long-term study by [Ketter et al. \(2010\)](#), sedation was present in 19.8% of patients. Dizziness is another troublesome side effect, and it may be associated with postural hypotension, an effect that is of even greater concern. As with sedation, dizziness can sometimes cause discontinuation of quetiapine therapy.

## Metabolic Effects

There is major concern about antipsychotic-induced weight gain and metabolic disturbances ([Allison et al. 1999](#); [Newcomer 2005](#); [Newcomer et al. 2002](#)). Quetiapine is clearly associated with weight gain, although the weight gain effect is not as great as that seen with clozapine or olanzapine. On the other hand, the weight-effects profile of quetiapine is not as favorable as that of ziprasidone or aripiprazole ([Newcomer 2005](#)) or that of the newer agents asenapine and lurasidone ([Allergan 2015](#); [Sunovion 2013](#)).

In the 8-week comparative study by [Zhong et al. \(2006\)](#), weight gain that was clinically significant (a 7% increase above baseline weight) was observed in 10.4% of patients taking quetiapine and in 10.5% of patients taking risperidone. In the Phase I CATIE study, quetiapine had a moderate effect on weight (and other aspects of the metabolic profile) compared with other agents ([Lieberman et al. 2005](#)). Those data are shown in [Table 27-2](#). In the first-episode CAFE study, quetiapine had a less favorable weight-effects profile compared with olanzapine or risperidone. Eighty percent of patients taking quetiapine gained weight, compared with 50% of those taking olanzapine and 2% of those taking risperidone. Interestingly, females taking quetiapine were less likely than males to gain weight in this 1-year study of patients treated for their first episode of psychosis ([Patel et al. 2009](#)). It is also important to consider quetiapine’s propensity to induce weight gain among bipolar patients (especially because these patients may also be taking lithium or valproic acid). In the 8-week EMBOLDEN I ([Young et al. 2010](#)) and EMBOLDEN II ([McElroy et al. 2010](#)) trials, weight gain of more than 7% body weight was present in 4.6% and 9%, respectively, of patients taking quetiapine 300 mg/day versus 8.3% and 11.3%, respectively, of those taking quetiapine 600 mg/day. In EMBOLDEN I and EMBOLDEN II, the average weight gains in quetiapine-treated patients were 0.6 kg and 1.1 kg, respectively, for the 300-mg/day groups and 0.8 kg and 1.7 kg, respectively, for the 600-mg/day groups.

**TABLE 27-2. Comparative metabolic profiles of antipsychotics in the Phase I CATIE schizophrenia trial: change from baseline**

Olanzapine	Quetiapine	Perphenazine	Risperidone	Ziprasidone	P value

*Note.* Hb=hemoglobin; SE=standard error. *P* values for laboratory values and for the change in weight are based on ranked analysis of covariance with adjustment for whether patient had a recent exacerbation in the preceding 3 months and the duration of exposure to the study drug in FIM. Mean values for metabolic factors (other than weight change) were also adjusted for duration of exposure to study drug.

Source. Adapted from [Lieberman et al. 2005](#).

In the bipolar depression study by [Calabrese et al. \(2005\)](#), the mean changes in glucose levels were 6 mg/dL and 3 mg/dL with quetiapine dosages of 600 mg/day and 300 mg/day, respectively. In the comparative study of quetiapine and risperidone in the treatment of schizophrenia ([Zhong et al. 2006](#)), the mean changes from baseline in fasting glucose

levels were 1.8 mg/dL with quetiapine and 5.6 mg/dL with risperidone. The metabolic profile of quetiapine appeared moderate in the Phase I CATIE schizophrenia study (see [Table 27-2](#)). [Newcomer et al. \(2009\)](#) conducted a euglycemic clamp study of quetiapine and found little evidence of insulin insensitivity. A recent meta-analysis by the Cochrane group involving head-to-head comparisons of SGAs ([Komossa et al. 2010](#)) found that quetiapine was associated with significantly greater cholesterol elevations than risperidone (mean difference 8.61 mg/dL) and ziprasidone (mean difference 16.01 mg/dL). In the CATIE Phase I trial ([Lieberman et al. 2005](#)), which included patients with chronic schizophrenia, quetiapine led to a mean change from baseline fasting triglyceride levels of +19.2 mg/dL, whereas a mean change of +42.9 mg/dL was observed for olanzapine, +8.3 mg/dL for perphenazine, -2.6 mg/dL for risperidone, and -18.1 mg/dL for ziprasidone. In a population of young patients with early psychosis treated with quetiapine, olanzapine, or risperidone, the CAFE study ([Patel et al. 2009](#)) found that elevations in fasting triglyceride levels at 52 weeks were significantly greater in quetiapine-treated patients than in risperidone-treated patients (44.3 vs. 8.2 ng/mL, respectively). [Correll et al. \(2014\)](#) reported baseline results from the pragmatic study Recovery After an Initial Schizophrenia Episode (RAISE). All patients were in their first episode of psychosis, with less than 6 months of exposure to antipsychotics. Use of quetiapine was associated with a high ratio of triglycerides to high-density lipoprotein (HDL) cholesterol. The extent to which patients traverse during treatment from a normative metabolic state to dysregulation is also informative. In the first-episode CAFE study, treatment-emergent metabolic syndrome was observed among 51 patients (13.4% of the population in a study where 4.3% met metabolic syndrome criteria at study onset), with a distribution of 22 patients taking olanzapine, 18 taking quetiapine, and 11 taking risperidone ([Patel et al. 2009](#)). Another recent study of antipsychotic use in adolescents found an elevated risk of type 2 diabetes mellitus, with longer duration of antipsychotic exposure and olanzapine use conferring greater risk ([Correll et al. 2014](#)). In another first-episode comparative study, [Pérez-Iglesias et al. \(2014\)](#) found that first-episode patients treated with quetiapine, aripiprazole, or ziprasidone gained weight over 12 weeks of treatment, with >7% weight increase noted for 32% of patients receiving quetiapine, 45% of those receiving aripiprazole, and 23% of those receiving ziprasidone. Quetiapine and aripiprazole were also associated with greater increases in total cholesterol and low-density lipoprotein (LDL) cholesterol. Overall, quetiapine appears to carry a risk of causing weight gain and other metabolic disturbances. The potential that quetiapine may preferentially raise triglycerides is noteworthy, given that this effect could be a harbinger for later insulin resistance. This observation merits further consideration and vigilance over time.

Quetiapine is associated with a low risk of raising prolactin levels ([Hamner et al. 1996](#); [Lieberman et al. 2005](#); [Small et al. 1997](#); [Zhong et al. 2006](#)).

## Extrapyramidal Side Effects

The low-EPS advantage of quetiapine is compelling and consistent across studies. In the Seroquel Patient Evaluation on Changing Treatment Relative to Usual Medication (SPECTRUM) switch study ([Larmo et al. 2005](#)), switching to quetiapine from haloperidol, olanzapine, or risperidone was associated with a robust reduction in EPS. This low propensity for EPS was also seen in the bipolar depression studies ([Calabrese et al. 2005](#); [Thase et al. 2006](#)).

## Cardiovascular Effects

Quetiapine's prescribing information ([AstraZeneca 2013a, 2013b](#)) carries a warning similar to that required in the prescribing information of many other antipsychotics concerning cardiovascular risks. The CATIE trial found no evidence of a heightened QTc risk with quetiapine relative to other SGAs and perphenazine ([Lieberman et al. 2005](#)). A curious and unsubstantiated claim is that quetiapine might have abuse potential ([Pierre et al. 2005](#); [Pinta and Taylor 2007](#)). This observation merits further consideration and vigilance.

## Other Effects

The potential of quetiapine to induce cataracts was studied in a pragmatic follow-up trial of patients ( $N=37$ ; mean age 23 years) with first-episode psychosis that included regular slit-lamp ophthalmological examinations ([Whitehorn et al. 2004](#)). After exposure to quetiapine 500–600 mg/day for a mean of 22.4 months, none of the patients developed any ocular changes. Most clinicians do not obtain specialist eye examinations when prescribing quetiapine.

Abnormalities in thyroid hormone levels were observed in the large premarketing trials of quetiapine ([Arvanitis and Miller 1997](#)). A small RCT did find lower total thyroid hormone levels with quetiapine use, but no significant changes in free thyroxine ( $T_4$ ) or thyroid-stimulating hormone (TSH) levels ([Kelly and Conley 2005](#)).

## Use During Pregnancy

As is the case with all SGAs, there is little information about the effects of quetiapine during pregnancy. A prospective study by [McKenna et al. \(2005\)](#) examined a sample of pregnant women in Canada, Israel, and England treated with SGAs, which was matched to a comparison group of pregnant women who were not exposed to these agents. Among them were 36 women treated with quetiapine. The pregnancy outcomes in the exposed and comparison groups were not significantly different, with the exceptions of the rate of low birth weight, which was 10% in exposed babies versus 2% in the comparison group ( $P=0.05$ ), and the rate of therapeutic abortions, which was 9.9% in exposed women versus 1.3% in the comparison group ( $P=0.003$ ). These findings suggest that atypical antipsychotics as a group are not associated with an increased risk for major malformations.

---

## Conclusion

---

Quetiapine is now a well-established and widely prescribed antipsychotic. As detailed earlier, there is strong evidence for its efficacy in all of the current FDA-approved indications. Quetiapine is also used extensively under circumstances not approved by the FDA (i.e., off-label use), and evidence for its efficacy in some of these uses has been reviewed in this chapter. Additional clinical trials of quetiapine are ongoing (<https://clinicaltrials.gov>).

## CHAPTER 28

# Risperidone and Paliperidone

Michele Hill, M.R.C.Psych.

Donald C. Goff, M.D.

---

### History and Discovery

---

A decade before clozapine was approved for marketing in the United States, Janssen Pharmaceuticals established a program to examine the potential role of serotonergic agents in schizophrenia. Early interest in serotonergic agents stemmed from preclinical literature demonstrating that both behavioral effects of dopamine receptor agonists and haloperidol-induced catalepsy could be modulated by serotonin 2 (5-HT<sub>2</sub>) receptor antagonists; in addition, the early butyrophenone derivative pipamperone, which was observed to reduce agitation and improve social activity in patients with severe depression, was found to possess primarily 5-HT<sub>2</sub> receptor antagonist activity ([Ansoms et al. 1977](#); [Leysen et al. 1978](#)).

In 1981, Janssen Pharmaceuticals developed setoperone, a 5-HT<sub>2</sub> receptor antagonist with weak dopamine 2 (D<sub>2</sub>) receptor antagonism that displayed antipsychotic effects and efficacy for negative symptoms in a preliminary open trial ([Ceulemans et al. 1985](#)). Janssen Pharmaceuticals additionally synthesized a selective 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptor antagonist, ritanserin, which was shown to decrease extrapyramidal side effects (EPS) when combined with haloperidol in rat studies. Ritanserin also was active in animal models of anxiety ([Colpaert et al. 1985](#); [Meert and Colpaert 1986](#)) and partially ameliorated the behavioral effects of lysergic acid diethylamide (LSD) ([Colpaert et al. 1985](#)). In placebo-controlled trials in patients with chronic schizophrenia, addition of ritanserin to first-generation antipsychotics (FGAs) improved negative symptoms and EPS ([Bersani et al. 1990](#); [Duinkerke et al. 1993](#); [Gelders 1989](#); [Reyntjens et al. 1986](#)). Concluding that 5-HT<sub>2</sub> receptor antagonism might improve the effectiveness of D<sub>2</sub> blockers, particularly for negative symptoms, and reduce EPS, but that it was not sufficiently effective as monotherapy, Paul Janssen and colleagues undertook development of risperidone, which combined potent 5-HT<sub>2A</sub> and D<sub>2</sub> receptor blockade.

After extensive preclinical characterization ([Janssen et al. 1988](#)), risperidone was first studied in clinical trials in 1986 and received U.S. Food and Drug Administration (FDA) approval for marketing in the United States in 1994. By the time risperidone became available to clinicians, the prominence of theories citing 5-HT<sub>2</sub> enhancement of D<sub>2</sub> receptor antagonism as a primary mechanism for clozapine's atypical properties ([Meltzer et al. 1989](#)), and the evidence from registration trials of reduced EPS and greater efficacy

compared with high-dose haloperidol, resulted in considerable enthusiasm for the first of the “serotonin-dopamine antagonists.” Risperidone was rapidly incorporated into clinical practice in the United States, where within 2 years it became the most frequently prescribed antipsychotic agent. In 2003, risperidone microspheres (Consta) received FDA approval as the first long-acting second-generation antipsychotic (SGA) designed for intramuscular (IM) injection. In December 2006, Janssen Pharmaceuticals introduced paliperidone (9-hydroxyrisperidone), the active metabolite of risperidone, formulated as an extended-release tablet marketed under the brand name Invega. Extended-release paliperidone is approved for the treatment of schizophrenia and schizoaffective disorder. A long-acting depot preparation, paliperidone palmitate (Sustenna), received FDA approval for schizophrenia in 2009 and for schizoaffective disorder in 2014; it was the first once-monthly depot formulation of an SGA to become available in the United States. In May 2015, a new formulation of paliperidone with a 3-month injection interval, paliperidone palmitate 3-month formulation (PP3M; Invega Trinza), was approved by the FDA for the treatment of schizophrenia under its priority review process. This formulation’s 3-month schedule provides the longest dosing interval available for patients with schizophrenia.

---

## Pharmacological Profile

---

Risperidone, or 3-[2-(4-[6-fluoro-1,2-benzisoxazol-3-yl]-1-piperidinyl)ethyl]-6,7,8,9-tetrahydro-2-methyl-4H-pyrido[1,2-a]pyrimidin-4-one, is a benzisoxazole derivative characterized by very high affinity for 5-HT<sub>2A</sub> receptors and moderately high affinity for D<sub>2</sub>, histamine 1 (H<sub>1</sub>), and  $\alpha_1$ - and  $\alpha_2$ -adrenergic receptors (Figure 28-1). In vitro, the affinity of risperidone for 5-HT<sub>2A</sub> receptors is roughly 10- to 20-fold greater than that for D<sub>2</sub> receptors (Leysen et al. 1994; Schotte et al. 1996); in vivo binding to rat striatal D<sub>2</sub> receptors occurs at a dosage 10 times higher than does binding to 5-HT<sub>2A</sub> receptors (Leysen et al. 1994). The affinity for 5-HT<sub>2A</sub> receptors is more than 100-fold greater than for other serotonin receptor subtypes. Risperidone’s active metabolite 9-hydroxyrisperidone (paliperidone) (Figure 28-2) has a similar receptor affinity profile, although paliperidone has lower affinity for  $\alpha_1$ - and  $\alpha_2$ -adrenergic receptors. Both risperidone and paliperidone display a high affinity for 5-HT<sub>2A</sub> receptors in rat brain tissue and for cloned human receptors expressed in COS-7 cells (Leysen et al. 1994). Risperidone binds to 5-HT<sub>2A</sub> receptors with approximately 20-fold greater affinity compared with clozapine and 170-fold greater affinity compared with haloperidol (Leysen et al. 1994).

**FIGURE 28-2.** Chemical structure of paliperidone.

The affinity of risperidone for  $D_2$  receptors is approximately 50-fold greater than that of clozapine and approximately 20%–50% that of haloperidol (Leysen et al. 1994) (Table 28-1). Binding affinity for  $D_2$  receptors was similar in rat mesolimbic and striatal tissue and in the long and short forms of cloned human  $D_2$  receptors expressed in embryonic kidney cells (Leysen et al. 1993a). The affinities of risperidone and paliperidone for dopamine<sub>4</sub> ( $D_4$ ) and dopamine<sub>1</sub> ( $D_1$ ) receptors are similar to those of clozapine and haloperidol (Leysen et al. 1994). Risperidone and paliperidone have essentially no affinity for muscarinic acetylcholine receptors and modest  $H_1$  receptor activity. Unlike haloperidol, risperidone does not bind to sigma sites (Leysen et al. 1994). However, compared with other agents, including paliperidone, risperidone has a relatively high affinity for  $\alpha_2$ -adrenergic receptors that is substantially greater than that of clozapine or any FGA and that approaches the affinity of phentolamine (Richelson 1996). The affinity of risperidone for  $\alpha_1$ -adrenergic receptors is roughly comparable to that of chlorpromazine and approximately 5 to 10 times greater than that of clozapine (Leysen et al. 1993b; Richelson 1996). The median effective dose ( $ED_{50}$ ) of risperidone required to inhibit  $D_2$ -mediated apomorphine-induced stereotypies in rats is 0.5 mg/kg; at this dose, approximately 40% of  $D_2$  receptors are occupied, as are 80% of 5-HT<sub>2A</sub> receptors, 50% of  $H_1$  receptors, 38% of  $\alpha_1$ -adrenergic receptors, and 10% of  $\alpha_2$ -adrenergic receptors (Leysen et al. 1994).

**TABLE 28-1. Receptor-binding affinities ( $K_i$  values, in nM) of representative antipsychotics in cloned human receptors and rat brain**

	Paliperidone	Risperidone	Haloperidol	Clozapine

<sup>b</sup>Rat brain.

Source. Adapted from [Schotte et al. 1996](#).

Several groups have studied the occupancy of D<sub>2</sub> and 5-HT<sub>2</sub> receptors in patients with schizophrenia, employing positron emission tomography (PET) or single-photon emission computed tomography (SPECT) ligand-binding techniques. [Kapur et al. \(1999\)](#) used PET to measure D<sub>2</sub> occupancy with <sup>11</sup>C-labeled raclopride and 5-HT<sub>2</sub> occupancy with <sup>18</sup>F-labeled setoperone in patients with chronic schizophrenia maintained on a stable clinician-determined dose of risperidone. The PET was performed 12–14 hours after the last dose of risperidone. Occupancy of D<sub>2</sub> receptors ranged from 63% to 89%; 50% occupancy was calculated to occur with a daily risperidone dose of 0.8 mg. Patients treated with risperidone (6 mg/day) exhibited a mean D<sub>2</sub> occupancy of 79%, which was consistent with the mean occupancy of 82% that was previously reported by [Nyberg et al. \(1999\)](#) and would be expected to exceed the putative threshold for EPS in some patients. A similar degree of D<sub>2</sub> occupancy was calculated to occur with olanzapine at approximately 30 mg daily ([Kapur et al. 1999](#)). A maximal 5-HT<sub>2</sub> occupancy of greater than 95% was achieved with risperidone at daily doses as low as 2–4 mg. In a small sample of patients treated biweekly for at least 10 weeks with risperidone microspheres (Consta), [Remington et al. \(2006\)](#) found that the 25-mg dose produced a mean D<sub>2</sub> occupancy of 54% (preinjection) and 71% (postinjection), whereas the 50-mg dose produced occupancy levels of 65% (preinjection) and 74% (postinjection). [Arakawa et al. \(2008\)](#) found a D<sub>2</sub> occupancy of 58% with paliperidone at 3 mg/day and 77% with 9 mg/day, consistent with clinical estimates that paliperidone is roughly half as potent as risperidone, perhaps due to reduced bioavailability ([de Leon et al. 2010](#)).

Preclinical characterization of risperidone in rats revealed more potent antiserotonergic activity compared with ritanserin in all tests ([Janssen et al. 1988](#)). For example, in reversal of tryptophan-induced effects in rats, risperidone was 6.4 times more potent than ritanserin for reversal of peripheral 5-HT<sub>2</sub>-mediated effects and 2.4 times more potent for reversal of centrally mediated 5-HT<sub>2</sub> effects ([Janssen et al. 1988](#)). Risperidone was also found to completely block discrimination of LSD, in contrast to the partial attenuation observed with ritanserin ([Meert et al. 1989](#)). Although risperidone demonstrated activity in all dopamine-mediated tests, the dose-response pattern differed from that of haloperidol ([Janssen et al. 1988](#)). The two drugs were roughly equipotent for inhibition of certain dopamine effects, such as amphetamine-induced oxygen hyperconsumption, whereas the dose of risperidone necessary to cause pronounced catalepsy in rats was 18-fold higher than that of haloperidol ([Janssen et al. 1988](#)). Risperidone depressed vertical and horizontal activity in rats at a dose 2–3 times greater than that of haloperidol but required doses more than 30 times greater than those of haloperidol to depress small motor movements ([Megens et al. 1988](#)).

---

## Pharmacokinetics and Disposition

---

Risperidone is rapidly absorbed after oral administration, with peak plasma levels achieved within 1 hour ([Heykants et al. 1994](#)). In early Phase I studies, risperidone demonstrated linear pharmacokinetics at dosages between 0.5 and 25 mg/day ([Mesotten et al. 1989](#); [Roose et al. 1988](#)).

After a single dose of the extended-release formulation of paliperidone (Invega), serum concentrations gradually increase until a maximum concentration is achieved approximately 24 hours after ingestion. Absorption of paliperidone is increased by approximately 50% when taken with a meal compared with the fasting state. Extended-release paliperidone also demonstrates dose-proportional pharmacokinetics within the recommended dosing range (3–12 mg/day).

Because risperidone lacks a hydroxyl group to which an ester can be bound for a traditional oil-based depot preparation, polymer microsphere technology was used to produce a slow-release injectable formulation. Risperidone microspheres do not begin to release appreciable amounts of drug until 3 weeks after injection and continue to release drug for approximately 4 weeks, with maximal drug release occurring after about 5 weeks.

Paliperidone palmitate is an esterified form of paliperidone and is poorly soluble in water. It dissolves slowly following IM injection, after which it is hydrolyzed to active paliperidone and absorbed into the systemic circulation. Systemic availability of paliperidone begins on day 1 and can last as long as 126 days after injection. Maximum blood levels are achieved a median of 13 days after injection. A dose of 75 mg/month is recommended, but in practice the modal dose is 100 mg/month ([Attard et al. 2014](#)). IM injection in the deltoid produces blood levels approximately 28% higher than those produced with gluteal injection. The 3-month formulation of paliperidone palmitate has an extended apparent elimination half-life that permits this longer dosing interval. Risperidone is 90% plasma protein bound, whereas paliperidone is 74% plasma protein bound ([Borison et al. 1994](#)). The absolute bioavailability of risperidone is about 100%; that of extended-release paliperidone is about 28%. Paliperidone may achieve relatively lower concentrations in the brain because of its higher affinity for the extruding P-glycoprotein transporter, which limits the amount of drug crossing the blood-brain barrier ([de Leon et al. 2010](#)).

Risperidone is metabolized by hydroxylation of the tetrahydropyridopyrimidinone ring at the seven and nine positions and by oxidative *N*-dealkylation ([Mannens et al. 1993](#)). The most important metabolite, 9-hydroxyrisperidone (paliperidone), accounts for up to 31% of the dose excreted in the urine. Because hydroxylation of risperidone is catalyzed by cytochrome P450 (CYP) 2D6, the half-life of the parent compound varies according to the relative activity of this enzyme. In extensive metabolizers, which include about 90% of Caucasians and as many as 99% of Asians, the half-life of risperidone is approximately 3 hours. Approximately 60% of paliperidone is excreted unchanged in the urine, and the remainder is metabolized by at least four different pathways (dealkylation, hydroxylation, dehydrogenation, and benzisoxazole scission), none of which accounts for more than 10% of the total. The terminal half-life of 9-hydroxyrisperidone (and of extended-release paliperidone) is 23 hours. Poor metabolizers metabolize risperidone primarily via oxidative pathways; the half-life may exceed 20 hours. In extensive metabolizers, radioactivity from <sup>14</sup>C-labeled risperidone is not detectable in plasma 24 hours after a single dose, whereas 9-hydroxyrisperidone accounts for 70%–80% of radioactivity. In poor metabolizers, risperidone is primarily responsible for radioactivity after 24 hours. In the U.S. multicenter

registration trial, the correlations between risperidone dose and serum risperidone and 9-hydroxyrisperidone concentrations were 0.59 and 0.88, respectively ([Anderson et al. 1993](#)). Because of paliperidone's longer half-life, its serum concentrations at steady state are approximately 5- to 10-fold higher than risperidone concentrations in CYP2D6 extensive metabolizers treated with risperidone ([de Leon et al. 2010](#)). However, in 2D6 poor metabolizers and patients concurrently taking 2D6 inhibitors, risperidone concentrations may be higher than paliperidone concentrations.

---

## Mechanism of Action

---

As previously discussed, risperidone was developed specifically to exploit the apparent pharmacological advantages of combining 5-HT<sub>2A</sub> receptor antagonism with D<sub>2</sub> receptor blockade. Selective 5-HT<sub>2A</sub> receptor antagonists administered alone have demonstrated activity in several animal models suggestive of antipsychotic effect, including blockade of both amphetamine- and phencyclidine (PCP)-induced locomotor activity ([Schmidt et al. 1995](#)). Dizocilpine-induced disruption of prepulse inhibition is also blocked by 5-HT<sub>2A</sub> receptor antagonists, suggesting that sensory gating deficits characteristic of schizophrenia and perhaps resulting from glutamatergic dysregulation might also benefit from the 5-HT<sub>2</sub> receptor antagonism of risperidone ([Varty et al. 1999](#)). The disruption of prepulse inhibition by dizocilpine (MK-801, a noncompetitive N-methyl-D-aspartate [NMDA] receptor antagonist) is attenuated by SGAs, but not by first-generation D<sub>2</sub> receptor blockers ([Geyer et al. 1990](#)). From a study in which the selective 5-HT<sub>2A</sub> receptor antagonist M100907 was added to low-dose raclopride (a selective D<sub>2</sub> receptor blocker), [Wadenberg et al. \(1998\)](#) concluded that 5-HT<sub>2A</sub> antagonism facilitates D<sub>2</sub> receptor antagonist blockade of conditioned avoidance, another behavioral model associated with antipsychotic efficacy, but does not block conditioned avoidance when administered alone.

One mechanism by which risperidone, paliperidone, and similar atypical agents might produce enhanced efficacy for negative symptoms and cognitive deficits and reduced risk for EPS is via 5-HT<sub>2A</sub> receptor modulation of dopamine neuronal firing and cortical dopamine release. Prefrontal dopaminergic hypoactivity has been postulated to underlie negative symptoms and cognitive deficits in schizophrenia ([Goff and Evins 1998](#)); both clozapine and ritanserin have been shown to increase dopamine release in prefrontal cortex, whereas haloperidol does not ([Busatto and Kerwin 1997](#)). Following 21 days of administration, risperidone, but not haloperidol, continued to increase dopamine turnover in the dorsal striatum and prefrontal cortex ([Stathis et al. 1996](#)). Ritanserin has been shown to enhance midbrain dopamine cell firing by blocking a tonic inhibitory serotonin input ([Ugedo et al. 1989](#)). Ritanserin also normalized ventral tegmental dopamine neuron firing patterns in rats after hypofrontality was induced by experimental cooling of the frontal cortex ([Svensson et al. 1989](#)).

[Svensson et al. \(1995\)](#) performed a series of elegant studies examining the impact of atypical antipsychotics on ventral tegmental dopamine firing patterns disrupted by glutamatergic NMDA receptor antagonists. In healthy human subjects, administration of the NMDA antagonist ketamine is widely regarded as a promising model for several clinical aspects of schizophrenia, including psychosis, negative symptoms, and cognitive deficits ([Goff and Coyle 2001](#); [Krystal et al. 1994](#)). In rats, administration of the NMDA channel blockers dizocilpine or PCP increased burst firing of ventral tegmental dopamine neurons predominantly projecting to limbic structures but reduced firing of mesocortical

tract dopamine neurons and disrupted firing patterns. Administration of ritanserin or clozapine preferentially enhanced firing of dopamine neurons with cortical projections, and when added to a D<sub>2</sub> blocker, ritanserin increased dopamine release in prefrontal cortex. In addition to modulating ventral tegmental dopamine neuron firing, risperidone also blocks 5-HT<sub>2</sub> receptors on inhibitory  $\gamma$ -aminobutyric acid (GABA)-ergic interneurons, which could also influence activity of cortical pyramidal neurons that are regulated by these local inhibitory circuits (Gellman and Aghajanian 1994).

In placebo-controlled clinical trials, 5-HT<sub>2</sub> receptor antagonists have shown efficacy in reducing antipsychotic-induced parkinsonism and akathisia (Duinkerke et al. 1993; Poyurovsky et al. 1999). This effect may reflect 5-HT<sub>2A</sub> antagonist effects on nigrostriatal dopamine release. When combined with haloperidol, selective 5-HT<sub>2</sub> receptor antagonists increase dopamine metabolism in the striatum and prevent an increase in D<sub>2</sub> receptor density, thereby possibly reducing the effects of D<sub>2</sub> receptor blockade and dopamine supersensitivity (Saller et al. 1990). These agents do not affect dopamine metabolism in the absence of D<sub>2</sub> blockade.

The relative importance of 5-HT<sub>2</sub> receptor antagonist activity in producing atypical characteristics is the subject of debate. As argued by Kapur and Seeman (2001) and Seeman (2002), most SGAs have dissociation constants for the D<sub>2</sub> receptor that are larger than the dissociation constant of dopamine. This “loose binding” to the D<sub>2</sub> receptor may allow displacement by endogenous dopamine and may contribute to a reduced liability for EPS and hyperprolactinemia. Unique among atypical agents, risperidone is “tightly bound” to the D<sub>2</sub> receptor, with a dissociation constant smaller than that of dopamine (Seeman 2002). A model for atypical antipsychotic mechanisms that emphasizes D<sub>2</sub> dissociation constants would predict that the apparent atypicality of risperidone, compared with that of haloperidol, reflects the reduced D<sub>2</sub> receptor occupancy achieved by more favorable dosing rather than the intrinsic pharmacological characteristics of risperidone. According to some binding data, a comparable clinical dosage of haloperidol would be approximately 4 mg/day, rather than 20 mg/day as used in the North American multicenter registration trial (Kapur et al. 1999). Consistent with this view, benefits of risperidone for negative symptoms and EPS were less apparent when compared with lower doses of haloperidol or with lower-potency FGAs (see “Indications and Efficacy” section later in this chapter) than when compared with high-dose haloperidol (20 mg/day).

An additional mechanism possibly contributing to the enhanced efficacy of risperidone and paliperidone is their considerable  $\alpha$ -adrenergic receptor antagonism. In a placebo-controlled augmentation trial, Litman et al. (1996) demonstrated significant improvement in psychosis and negative symptoms with the  $\alpha_2$ -adrenergic receptor antagonist idazoxan when it was added to FGAs. Idazoxan has been shown to increase dopamine levels in the rat medial prefrontal cortex (Hertel et al. 1999). In aged rats (Haapalinna et al. 2000) and in patients with frontal dementias (Coull et al. 1996),  $\alpha_2$ -adrenergic receptor blockers have also been reported to improve cognitive functioning. Svensson et al. (1995) found that prazosin, an  $\alpha_1$  receptor antagonist, inhibited both the behavioral activation and the increase in mesolimbic dopamine release produced by PCP or MK-801.

In summary, risperidone and paliperidone possess at least two mechanisms that may confer atypical characteristics. 5-HT<sub>2A</sub> receptor antagonism partially protects against D<sub>2</sub> antagonist-induced neurological side effects and may improve negative symptoms and cognitive functioning via modulation of mesocortical dopamine activity. In addition, blockade of adrenoceptors may further increase prefrontal cortical activity and could

enhance antipsychotic efficacy by modulation of mesolimbic dopamine activity. Unlike other SGA agents, risperidone and paliperidone do not differ from FGAs in their dissociation constant for the D<sub>2</sub> receptor; this feature perhaps accounts for the risk of EPS at high doses, as well as their greater propensity to cause hyperprolactinemia.

## Indications and Efficacy

Risperidone is approved by the FDA for the treatment of schizophrenia, bipolar mania, and irritability associated with autism. In August 2007, the indication for schizophrenia was extended to include adolescents ages 13–17 years, and the bipolar mania indication was extended to include children 10–17 years of age. The risperidone microsphere formulation (Consta long-acting injectable [LAI]) is approved for the treatment of schizophrenia and bipolar I disorder. Extended-release oral paliperidone (Invega) is approved for the treatment of schizophrenia and schizoaffective disorder, LAI paliperidone palmitate (Sustenna) is approved for the treatment of schizophrenia and schizoaffective disorder, and paliperidone palmitate 3-month injection formulation (Invega Trinza) is approved for the treatment of schizophrenia.

## Schizophrenia

### Clinical Trial Results for Risperidone

**Eight-week trials.** In the two North American registration trials ([Chouinard et al. 1993](#); [Marder and Meibach 1994](#)), a total of 513 patients with chronic schizophrenia were randomly assigned to an 8-week double-blind, fixed-dose, placebo-controlled comparison of risperidone (2, 6, 10, or 16 mg/day) versus haloperidol (20 mg/day). Risperidone dosages of 6, 10, and 16 mg/day produced significantly greater reductions, as compared with haloperidol, in each of the five domains of the Positive and Negative Syndrome Scale (PANSS), derived by principal-components analysis ([Marder et al. 1997](#)), and significantly higher response rates, defined as a 20% reduction in the PANSS total score. Effect sizes representing the difference in change scores between risperidone (6 mg/day) and haloperidol, although statistically significant, were uniformly small by Cohen’s classification system ([Cohen 1988](#)): negative symptoms 0.31; positive symptoms 0.26; disorganized thoughts 0.22; uncontrolled hostility/excitement 0.29; and anxiety/depression 0.30 ([Table 28–2](#)). Severity of EPS was greater with haloperidol than with risperidone; further statistical analysis suggested that differences in EPS rates did not significantly influence the differences in PANSS subscale ratings ([Marder et al. 1997](#)). In fact, risperidone 10 mg/day and 16 mg/day produced improvements in negative symptoms equivalent to those seen with risperidone 6 mg/day, despite increased EPS at the higher dosages of risperidone.

**TABLE 28–2. Effect sizes on Positive and Negative Syndrome Scale (PANSS) symptom dimensions: North American trials (N=513)**

Adjusted mean change scores	Risperidone 6
-----------------------------	---------------

Source. Adapted from [Marder et al. 1997](#).

	Adjusted mean change scores			Risperidone 6	
	Placebo	Risperidone 6 mg/day	Haloperidol 20 mg/day	Effect size vs. placebo	Effect size vs. halo
PANSS total	-3.8	-18.6	-5.1	0.53	0.0
Negative	0.2	-3.4	-0.1	0.27	0.0
Positive	0.9	-5.7	-2.3	0.48	0.0
Disorganized thought	0.1	-4.6	-0.2	0.43	0.0
Hostility/excitement	0.2	-2.5	-0.1	0.47	0.0
Anxiety/depression	-0.1	-2.5	-0.6	0.36	0.0

Source. Adapted from [Marder et al. 1997](#).

When risperidone (1, 4, 8, 12, and 16 mg/day) was compared with haloperidol (10 mg/day) in a large 8-week European trial involving 1,362 subjects with schizophrenia ([Peuskens 1995](#)), PANSS subscale change scores among risperidone-treated subjects indicated a preferential response to daily doses of 4 mg and 8 mg. However, neither the risperidone group taken as a whole nor individual risperidone doses achieved significantly better outcomes than haloperidol (10 mg/day) on any measure except for EPS, suggesting that the clinical superiority of risperidone over haloperidol in previous studies may have resulted from excessively high dosing of the comparator.

**CATIE.** In the National Institute of Mental Health-funded Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE; [Stroup et al. 2003](#)), 1,432 patients with chronic schizophrenia were randomly assigned to double-blind, flexibly dosed treatment for 18 months with risperidone, olanzapine, quetiapine, ziprasidone, or the FGA comparator perphenazine. Clinicians could adjust the dosage of each drug by prescribing 1–4 capsules daily; risperidone capsules contained 1.5 mg, and the mean daily dose administered in the study was 3.9 mg. Based on the primary outcome measure, time to all-cause discontinuation, risperidone was less effective than olanzapine (mean dosage 20 mg/day) and comparable in effectiveness to perphenazine, quetiapine, and ziprasidone ([Lieberman et al. 2005](#)). Although differences in rates of dropout due to intolerance did not reach statistical significance, risperidone consistently was the best-tolerated drug, particularly in subjects who had discontinued their first-assigned drug due to intolerance.

**Maintenance treatment.** [Csernansky et al. \(2002\)](#) randomly assigned 365 patients with stable schizophrenia or schizoaffective disorder to clinician-determined flexible dosing with risperidone or haloperidol for a minimum of 1 year. Kaplan-Meier estimates of the risk of relapse at the end of the study were 34% with risperidone versus 60% with haloperidol, a highly significant difference ( $P=0.001$ ). The LAI risperidone microsphere formulation (Consta) at fixed doses of 25 mg, 50 mg, and 75 mg administered biweekly was superior in efficacy to placebo in a 12-week trial ([Kane et al. 2003](#)), but the 75-mg dose was not developed further due to an increased rate of EPS. In a 52-week maintenance study comparing fixed doses of risperidone microspheres administered every 2 weeks, the 25-mg dose was associated with a relapse rate of 21.6% and the 50-mg dose was associated with a 14.9% relapse rate ( $P=0.06$ ) ([Simpson et al. 2006](#)). Comparisons of risperidone microspheres against oral SGAs have failed to demonstrate greater benefit with the LAI formulation. In 12-month randomized trials, the efficacy of risperidone

microspheres was similar to that of oral risperidone ( $n=50$ ; [Bai et al. 2007](#)), oral olanzapine ( $n=377$ ; [Keks et al. 2007](#)), or clinician's choice of an oral antipsychotic other than clozapine ( $n=369$ ; [Rosenheck et al. 2011](#)). By contrast, a nationwide cohort study using national databases in Norway found risperidone microspheres to be more effective in preventing readmission following a first hospitalization compared with oral risperidone and other oral antipsychotics with the exception of olanzapine and clozapine ([Tiihonen et al. 2011](#)). Because antipsychotic treatment in this naturalistic study was not randomized, conclusions are limited; nonetheless, the advantage found with depot formulations may reflect performance under typical clinical conditions.

**Cognitive functioning in schizophrenia.** Several early studies suggested that risperidone might enhance cognitive functioning, particularly verbal working memory, compared with haloperidol ([Green et al. 1997](#); [Harvey et al. 2005](#)). A large double-blind trial that examined cognitive effects in 414 chronic schizophrenia patients treated for 52 weeks with risperidone (mean dosage 5.2 mg/day), olanzapine (12.3 mg/day), and haloperidol (8.2 mg/day) found no difference between treatments on the composite cognitive score, although risperidone and olanzapine were superior to haloperidol in a secondary analysis of completers ([Keefe et al. 2006](#)). When compared with low-dose haloperidol (mean dosage 5 mg/day), no cognitive advantage was found for risperidone ([Green et al. 2002](#)). In addition, in the CATIE, neither risperidone nor any other SGA demonstrated cognitive benefit compared with the FGA agent perphenazine ([Keefe et al. 2007](#)). A study in medication-naïve patients found similar overall cognitive improvement with risperidone and olanzapine ([Cuesta et al. 2009](#)); however, another study of risperidone in medication-naïve patients reported impairments of spatial working memory ([Reilly et al. 2006](#)) and procedural memory ([Harris et al. 2009](#)).

**First-episode and treatment-refractory schizophrenia.** Risperidone has been found to be well tolerated and effective in subgroups of patients with schizophrenia, including first-episode patients and elderly patients. In a 4-month double-blind trial comparing risperidone (mean dosage 3.9 mg/day) and olanzapine (mean dosage 11.8 mg/day) in 112 first-episode patients, both treatments were well tolerated, with an overall completion rate of 72% ([Robinson et al. 2006](#)). Response rates did not differ significantly between risperidone (54%) and olanzapine (44%), although patients who responded to risperidone were significantly more likely to retain their response. A recent 12-month double-blind trial comparing oral risperidone with LAI risperidone in 86 patients with recent-onset schizophrenia showed significantly lower relapse rates in the patients receiving the depot formulation ([Subotnik et al. 2015](#)). However, another randomized controlled trial of 85 first-episode patients found oral SGAs and LAI risperidone to be equally effective and to have similar safety profiles ([Malla et al. 2013](#)). This finding implies that LAI risperidone is a safe, effective treatment option in this population, although not necessarily the treatment of first choice.

Experience in patients with treatment-resistant schizophrenia has been less consistent. In the U.S. multicenter registration study, [Marder and Meibach \(1994\)](#) found that patients who were presumed to have failed to respond to FGAs, on the basis of a history of hospitalization for at least 6 months prior to study entry, did not respond to haloperidol (20 mg/day) but did display significant response to risperidone (6 mg/day and 16 mg/day) compared with placebo. [Wirshing et al. \(1999\)](#) reported significant improvement with risperidone (6 mg/day) compared with haloperidol (15 mg/day) during a 4-week fixed-dose trial in 67 patients with schizophrenia and a history of treatment resistance. In contrast, [Volavka et al. \(2002\)](#) found no difference between high-dose risperidone (8–16 mg/day)

and haloperidol (10–20 mg/day) in patients established by history to be treatment resistant to FGAs. In the CATIE, risperidone was more effective than quetiapine but did not differ from olanzapine and ziprasidone in patients who discontinued their first-assigned SGA medication due to lack of efficacy (Stroup et al. 2006). In contrast, patients who discontinued perphenazine (for any reason) subsequently did better on quetiapine or olanzapine than they did on risperidone (Stroup et al. 2007). Two meta-analyses comparing FGAs and SGAs suggested an advantage for risperidone over older drugs (Davis et al. 2003; Leucht et al. 2009), and a recent network meta-analysis broadly confirmed this suggestion (Leucht et al. 2013).

### Clinical Trial Results for Paliperidone

In a 6-week trial in acutely ill schizophrenia patients, extended-release paliperidone (Invega) at dosages of 6, 9, and 12 mg/day was more effective than placebo (Kane et al. 2007), and in a flexibly dosed trial (9–15 mg/day), extended-release paliperidone significantly reduced relapse compared with placebo (Kramer et al. 2007). Combined results from three placebo-controlled trials involving 1,326 acutely ill schizophrenia patients found significant improvement across a daily dosage range of 3–15 mg (Meltzer et al. 2008). Three studies compared paliperidone with olanzapine 10 mg/day and found no difference in efficacy, but paliperidone was associated with more movement disorders and less weight gain (Nussbaum and Stroup 2008). The network meta-analysis by Leucht et al. (2013) concluded that paliperidone was significantly less effective than clozapine, amisulpride, and olanzapine but not risperidone, although unlike risperidone, paliperidone failed to demonstrate superiority over older drugs.

LAI paliperidone palmitate administered every 4 weeks has been demonstrated to be more effective than placebo (Hough et al. 2010; Kramer et al. 2010; Nasrallah et al. 2010; Takahashi et al. 2013) and to be similar in efficacy to risperidone microspheres administered every 2 weeks (Pandina et al. 2011), although the latter finding was not replicated in another study (Fleischhacker et al. 2012). A randomized clinical trial comparing LAI paliperidone palmitate with depot haloperidol administered in a matched loading-dose schedule (McEvoy et al. 2014) showed that the two drugs were equally effective in preventing relapse.

A Phase III clinical trial of paliperidone palmitate 3-month formulation (Invega Trinza) versus placebo was terminated early after the interim analysis clearly demonstrated the superior efficacy of PP3M (hazard ratio=3.45; 95% confidence interval=1.73–6.88;  $P<0.001$ ) (Berwaerts et al. 2015).

A second Phase III randomized, double-blind noninferiority study ( $N=1,016$ ) comparing PP3M with paliperidone palmitate 1-month formulation (PP1M) found no differences in efficacy, relapse rates, or side-effect profiles between the two formulations (Savitz et al. 2016).

## Mood Disorders

Six controlled trials of 3–4 weeks' duration that included a total of 1,343 patients have examined the efficacy of risperidone as monotherapy or in combination with a mood stabilizer for the acute treatment of bipolar mania (Rendell et al. 2006). As monotherapy and in combination, risperidone was more effective than placebo and similar in efficacy to haloperidol but produced more weight gain and fewer EPS (Rendell et al. 2006). In a placebo-controlled trial of open-label risperidone LAI microspheres in the maintenance treatment of bipolar I disorder, patients ( $n=303$ ) with manic or mixed episodes who

maintained response during a preceding 26-week period of risperidone following an initial 3-week period of oral risperidone were randomly allocated to placebo injections or continued treatment with LAI risperidone for up to 24 months. A switch to placebo injections significantly shortened the time to recurrence of manic episodes, but not depressive episodes ([Quiroz et al. 2010](#)).

Risperidone 1–2 mg/day was evaluated as an adjunct to antidepressant therapy in a 4-week placebo-controlled trial in 174 antidepressant-resistant patients with major depressive disorder recruited from 19 primary care and psychiatric centers ([Mahmoud et al. 2007](#)). Risperidone significantly lowered ratings of depressive symptoms compared with placebo. Remission rates were 25% with risperidone versus 11% with placebo ( $P=0.004$ ). Risperidone was well tolerated, with an 81% completion rate (vs. 88% with placebo).

## Autism Spectrum Disorder

Risperidone also was studied in a large 8-week placebo-controlled trial in 101 children and adolescents (ages 5–17 years) with DSM-IV ([American Psychiatric Association 1994](#))-defined autistic disorder accompanied by severe tantrums, aggression, or self-injurious behavior ([McCracken et al. 2002](#)). Flexible dosing with risperidone (range=0.5–3.5 mg/day; mean dosage=1.2 mg/day) resulted in a mean reduction of 57% in irritability, compared with a decrease of 14% in the placebo group, and the response rate was 69% with risperidone versus 12% with placebo. In a study of 32 children (ages 5–17 years) with DSM-IV autistic disorder who were treated for 4 months with open-label risperidone (mean dosage 2 mg/day), those who continued treatment with risperidone during the second study arm, an 8-week double-blind substitution trial, had much lower relapse rates compared with patients who were switched to placebo ([Research Units on Pediatric Psychopharmacology Autism Network 2005](#)). Risperidone at a mean dosage of 2 mg/day was also found to be effective compared with placebo in a study of 31 adults with DSM-IV autistic disorder or pervasive developmental disorder not otherwise specified ([McDougle et al. 1998](#)). In these studies, risperidone improved irritability and restricted, repetitive, and stereotyped behavioral problems associated with autism but was not effective for social or language deficits ([McDougle et al. 2005](#)). Risperidone at a dosage of 0.02–0.06 mg/kg was found to be well tolerated and effective for disruptive behaviors in children with low intelligence (IQ between 36 and 84) in a 6-week placebo-controlled trial ([Aman et al. 2002](#)).

## Other Disorders

### Generalized Anxiety Disorder

In a 4-week placebo-controlled add-on trial of low-dose risperidone in 417 patients with persistence of generalized anxiety disorder symptoms despite 8 weeks of anxiolytic therapy, no benefit from risperidone was found in the primary analysis; however, risperidone was associated with greater improvement in patients with moderate or severe anxiety at baseline ([Pandina et al. 2007](#)). Risperidone was highly effective for obsessive-compulsive disorder symptoms in a 6-week placebo-controlled trial in 36 adults prospectively confirmed to be nonresponsive to treatment with a selective serotonin reuptake inhibitor ([McDougle et al. 2000](#)). Symptoms of anxiety and depression also

responded to risperidone compared with placebo. Fifty percent of risperidone-treated patients responded (mean dosage 2.2 mg/day), compared with none in the placebo group.

### Alzheimer's Disease

In the CATIE–Alzheimer's Disease (CATIE-AD) study, risperidone had the longest time to discontinuation due to lack of effectiveness (27 weeks) among the agents studied; comparison results were 22 weeks for olanzapine, 9 weeks for quetiapine, and 9 weeks for placebo ([Schneider et al. 2006](#)). However, because of poor tolerability, none of the three antipsychotics differed from placebo on time to all-cause discontinuation.

## Side Effects and Toxicology

Risperidone shares class warnings with other SGAs in the United States, including the risks of tardive dyskinesia, neuroleptic malignant syndrome, and hyperglycemia and diabetes, as well as the risk of increased mortality in elderly patients with dementia-related psychosis. However, risperidone generally has been very well tolerated in clinical trials. In the U.S. multicenter trial reported by [Marder and Meibach \(1994\)](#), only headache and dizziness were significantly more frequent with risperidone (6 mg/day) compared with placebo, whereas the group receiving risperidone (16 mg/day) treatment also reported more EPS and dyspepsia than did the group receiving placebo ([Table 28-3](#)). Fatigue, sedation, accommodation disturbances, orthostatic dizziness, palpitations or tachycardia, weight gain, diminished sexual desire, and erectile dysfunction displayed a statistically significant relationship to risperidone dose, although most were not significantly elevated compared with placebo. In a flexible-dose relapse prevention study reported by [Csernansky et al. \(2002\)](#), no side effects were more frequent with risperidone, compared with haloperidol, although risperidone produced significantly greater weight gain. In a flexibly dosed, placebo-controlled trial of risperidone for children with disruptive behavior, risperidone (mean dosage 1.2 mg/day) produced more somnolence, headache, vomiting, dyspepsia, weight gain, and prolactin elevation than did placebo; most side effects were rated mild to moderate and did not adversely affect compliance ([Aman et al. 2002](#)).

**TABLE 28-3. Side effects reported by patients with schizophrenia receiving placebo, risperidone, or haloperidol in the U.S. multicenter trial**

	Percentage of patients

## Metabolic Effects

Weight gain with risperidone is intermediate—that is, the degree of weight gain is between that associated with agents like molindone, amisulpride, and ziprasidone, which appear to be relatively weight neutral, and that associated with agents like clozapine, olanzapine, and low-potency phenothiazines ([Rummel-Kluge et al. 2010](#); [Sikich et al. 2008](#)). In a meta-analysis of controlled trials, [Allison et al. \(1999\)](#), using a random effects model, estimated the mean weight gain at 10 weeks with risperidone to be 2.0 kg, compared with 0.5 kg with haloperidol, 3.5 kg with olanzapine, and 4.0 kg with clozapine. In the CATIE, in which risperidone had the lowest rate of discontinuation due to side effects, risperidone treatment was associated with a mean monthly weight gain of 0.4 lb, olanzapine with 2.0 lbs, and quetiapine with 0.5 lb; by contrast, perphenazine and ziprasidone were associated with a mean monthly weight *loss* of 0.2 lb and 0.3 lb, respectively ([Lieberman et al. 2005](#)). Although determining the risk for hyperglycemia is complex, and results of studies have not been completely consistent, it appears that risperidone does not produce insulin resistance to the degree associated with olanzapine and clozapine ([American Diabetes Association et al. 2004](#); [Henderson et al. 2006](#); [Lieberman et al. 2005](#)). A meta-analysis of head-to-head comparisons of SGAs found that risperidone produced more cholesterol elevation than aripiprazole and ziprasidone and less elevation than olanzapine and quetiapine ([Rummel-Kluge et al. 2010](#)). Metabolic side effects in children tend to be more severe than those in adults; for example, in one study of pediatric patients younger than 20 years, risperidone produced a mean weight gain of 5.3 kg (11.7 lb) over the 12-week treatment period ([Correll et al. 2009](#)). Metabolic side effects with paliperidone appear to be similar to those with risperidone.

## Extrapyramidal Side Effects

Significant reductions in EPS with risperidone compared with high-dose haloperidol were a consistent finding in the North American trials ([Chouinard et al. 1993](#); [Marder and Meibach 1994](#)). Measurement of EPS in the placebo group was complicated because 25% of the subjects were receiving depot antipsychotics prior to enrollment. Risperidone produced significantly fewer parkinsonian side effects than did haloperidol (20 mg/day), based on several measures, including self-report, change scores on the Extrapyramidal Symptom Rating Scale (ESRS), and use of anticholinergic medication. Patients receiving risperidone (2 mg/day and 6 mg/day) did not differ from the group receiving placebo in mean ratings of parkinsonism and in the use of anticholinergic medication. Parkinsonism change scores were significantly correlated with the risperidone dosage ( $r=0.94$ ); however, risperidone (16 mg/day) was associated with fewer parkinsonian side effects than was haloperidol. Dystonia occurred in six of the patients treated with risperidone (1.7%) versus two of the patients treated with haloperidol (2.4%). Dystonia rates did not differ between treatment groups, and the rates did not exhibit a relationship to risperidone dosage.

In the large European multicenter trial, maximum ratings of parkinsonism, hyperkinesia, and dystonia were greater with haloperidol (10 mg/day) than with all dosages of risperidone (maximum of 12 mg/day), and anticholinergic dosing was accordingly higher in the group treated with haloperidol ([Peuskens 1995](#)). Similarly, in a flexible-dose comparison of risperidone (mean dosage 4.9 mg/day) and haloperidol (mean dosage 11.7 mg/day) for prevention of relapse, EPS rates and use of anticholinergic medication significantly favored the group taking risperidone ([Csernansky et al. 2002](#)). However, in a smaller double-blind, flexible-dose trial comparing risperidone (5–15 mg/day) and the moderate-potency FGA agent perphenazine (16–48 mg/day) in 107 patients, no difference in EPS rates was observed ([Høyberg et al. 1993](#)), indicating that the potency of the comparator agent may in part determine the relative benefit of risperidone for EPS. Of interest, in a study of low-dose risperidone (mean dosage 1.2 mg/day) in children with behavioral disorders, ratings of EPS did not differ between risperidone and placebo ([Aman et al. 2002](#)). No differences in EPS ratings were found among any treatment groups in the CATIE ([Lieberman et al. 2005](#)), although discontinuation rates due to EPS significantly differed, with perphenazine producing the highest discontinuation rate (8%) and olanzapine (2%), risperidone (3%), and quetiapine (3%) producing the lowest.

The experience with tardive dyskinesia (TD) in patients treated with risperidone has been promising. [Jeste et al. \(1999\)](#) randomly treated 122 elderly patients with low-dosage haloperidol (median daily dose 1 mg) versus risperidone (median daily dose 1 mg). The very high rates of treatment-emergent TD typically found in geriatric patients make this sample a sensitive assay for TD risk. After 9 months, treatment-emergent TD rates were 30% with haloperidol versus less than 5% with risperidone. Risperidone was also noted to decrease dyskinetic movements compared with haloperidol in a Canadian multicenter trial reported by [Chouinard et al. \(1993\)](#), and it was associated with a treatment-emergent TD rate of 0.6%, compared with a rate of 2.7% with haloperidol, in a relapse prevention trial reported by [Csernansky et al. \(2002\)](#).

## Hyperprolactinemia

Unlike other SGA agents, risperidone and paliperidone substantially increase serum prolactin levels—in some studies, to a greater degree than does haloperidol ([Kearns et al.](#)

2000; Markianos et al. 1999)—although prolactin levels may decrease over time (Eberhard et al. 2007; Findling et al. 2003). The relationship between serum prolactin concentrations and clinical side effects remains somewhat unclear, however. Kleinberg et al. (1999) analyzed combined results from the North American and European multicenter registration trials, which included plasma prolactin concentrations from 841 patients and clinical ratings of symptoms associated with hyperprolactinemia from 1,884 patients. Mean prolactin levels significantly correlated with risperidone dosage; risperidone 6 mg/day produced elevations roughly comparable to those seen with haloperidol 20 mg/day and significantly higher than those seen with haloperidol 10 mg/day. The combined incidence of amenorrhea and galactorrhea in women, which varied between 8% and 12%, was similar for all dosages of risperidone and haloperidol (10 mg/day). Because symptom frequencies were available only for 14 women treated with placebo, comparisons with placebo were not informative. Sexual dysfunction or gynecomastia occurred in 15% of men treated with risperidone (4–6 mg/day), compared with 14% of men treated with haloperidol (10 mg/day) and 8% of men in the placebo group. Compared with placebo, ejaculatory dysfunction was significantly more frequent only in the group treated with risperidone (12–16 mg/day). Mean plasma prolactin levels were not significantly related to clinical side effects for either men or women. Decreased libido also did not differ between treatment groups and did not correlate with plasma prolactin levels. In the CATIE, prolactin levels increased by a mean of 15.4 ng/mL with risperidone, compared with a 0.4-ng/mL mean elevation with perphenazine and decreases of 4.5–9.3 ng/mL with the other SGAs (Lieberman et al. 2005). Despite having significantly higher serum prolactin concentrations, patients treated with risperidone did not report significantly higher rates of sexual dysfunction, gynecomastia, galactorrhea, or irregular menses.

Two reports of clinical trials with extended-release paliperidone have indicated low levels of prolactin-related side effects (1% and 4%) (Kane et al. 2007; Kramer et al. 2007). However, in the one publication that reported prolactin levels, substantial increases in mean plasma prolactin concentrations were observed (males: 17.4 ng/mL at baseline to 45.3 ng/mL at week 6; females: 38.0 ng/mL to 124.5 ng/mL) (Kane et al. 2007). A 13-week comparison of paliperidone palmitate with risperidone microspheres reported that paliperidone palmitate was associated with moderately higher elevations from baseline in prolactin levels compared with risperidone (women: 21.8 vs. 15.6 ng/mL; men: 9.4 vs. 6.0 ng/mL) (Pandina et al. 2011); however, another study found that the proportion of patients with abnormally elevated prolactin levels was higher in the group receiving LAI risperidone than in that receiving paliperidone palmitate (Fleischhacker et al. 2012). Two preliminary studies with risperidone found that plasma prolactin concentrations correlated with 9-hydroxyrisperidone (paliperidone) concentrations and not with risperidone concentrations (Melkersson 2006; Troost et al. 2007). The ratio of 9-hydroxyrisperidone levels to risperidone levels also correlated with prolactin concentration (Troost et al. 2007); in agreement with this finding, rapid metabolizers of CYP2D6 were found to have higher prolactin concentrations than poor metabolizers (Troost et al. 2007).

## Cardiovascular Effects

Because of relatively high affinities for adrenoreceptors, risperidone would be expected to produce orthostatic hypotension. However, by following a 3- to 7-day dosage escalation schedule, initial postural hypotension and tachycardia have been avoided in clinical trials, with only rare cases of hypotension and syncope reported (Chouinard et al. 1993; Marder

and Meibach 1994). Risperidone has very modest effects on cardiac conduction. No significant prolongation of the QTc interval was detected at dosages of up to 25 mg/day in early safety trials, and no relationship between QTc interval and risperidone dose was apparent (Mesotten et al. 1989). In the CATIE, risperidone was associated with the least QTc prolongation (mean 0.2 msec) and quetiapine with the most (mean 5.9 msec), although differences were not statistically significant (Lieberman et al. 2005). A mean QTc prolongation of 10 msec, measured after peak absorption of risperidone (16 mg/day), was found in a study comparing SGAs and FGAs, according to data filed with the FDA by Pfizer Inc. (Harrigan et al. 2004). In a retrospective cohort study of Medicaid enrollees in Tennessee, risperidone was associated with a 2.9-fold increase in rate of sudden cardiac death, compared with a 1.61-fold increase with haloperidol and a 3.67-fold increase with clozapine (Ray et al. 2009).

## High Dose and Overdose

Mesotten et al. (1989) reported the results of a safety trial involving 17 inpatients with psychosis in which, following a washout of previous medication, risperidone was started at 10 mg/day, and the dosage was then increased weekly by 5 mg/day to a maximum of 25 mg/day. Despite extremely high doses, sedation was the only prominent side effect. Although risperidone does not bind significantly to muscarinic cholinergic receptors, transient dry mouth, blurred vision, and urinary retention were observed in individual subjects. Palpitations occurred in two subjects. Heart rate significantly increased during the trial, and blood pressure slightly decreased; however, no cases of significant hypotension were reported. An endocrine battery, including plasma triiodothyronine, thyroid-stimulating hormone, growth hormone, prolactin, follicle-stimulating hormone, luteinizing hormone, and cortisol levels, was performed, and only prolactin was found to be affected. Reported overdoses with risperidone have generally been benign, with moderate QT prolongation and no serious cardiac complications (Brown et al. 1993; Lo Vecchio et al. 1996).

---

## Drug-Drug Interactions

---

Because CYP2D6 status affects the half-life of risperidone and the relative ratio of risperidone to 9-hydroxyrisperidone in plasma, the total serum concentration of the “active moiety,” or the sum of the concentrations of risperidone and 9-hydroxyrisperidone, may be significantly increased with addition of a CYP2D6 inhibitor (e.g., fluoxetine) in rapid metabolizers but not in poor metabolizers (Bondolfi et al. 2002; Spina et al. 2002). In one study of 9 patients treated with risperidone, addition of fluoxetine resulted in a 75% increase in blood levels of the active moiety (risperidone+9-hydroxyrisperidone); two patients developed parkinsonian side effects (Spina et al. 2002). Paliperidone plasma concentrations are not influenced by CYP2D6 status, nor are paliperidone plasma concentrations likely to be affected by drug-drug interactions. It has been hypothesized that the addition of a CYP2D6 inhibitor (e.g., fluoxetine) could decrease risperidone-induced prolactin elevation by increasing the ratio of risperidone to 9-hydroxyrisperidone (Troost et al. 2007), although this has not been rigorously tested.

---

## Conclusion

---

Risperidone was the first antipsychotic agent developed specifically to exploit the clinical advantages of combined  $D_2$  and  $5-HT_{A2}$  receptor antagonism.  $\alpha$ -Adrenergic antagonism additionally may contribute to the antipsychotic and cognition-enhancing effects of risperidone. Risperidone's active metabolite, paliperidone, is pharmacologically quite similar to the parent drug and comprises roughly 80%–90% of the serum concentration of the active moiety (risperidone + paliperidone) in most patients treated with risperidone. Risperidone and paliperidone are generally quite well tolerated, producing moderate weight gain and mild sedation. Initial dosage titration is necessary to prevent orthostatic blood pressure changes and dizziness, although this may be less necessary with extended-release paliperidone. EPS are dose related and are typically less common with risperidone than with haloperidol but more common with risperidone compared with other SGAs. Risperidone and paliperidone markedly elevate prolactin levels, although the relationship between plasma prolactin concentrations and clinical symptoms is complex. The efficacy of risperidone was initially established in comparison with high-dose haloperidol, against which it was significantly more effective for all five symptom clusters derived from the PANSS. However, the magnitude of difference in effect size was not large for individual symptom clusters. In the CATIE, risperidone (at a mean daily dosage of 3.9 mg) did not differ from perphenazine in rates of discontinuation due to lack of effectiveness but was less effective than olanzapine (Lieberman et al. 2005). The risperidone microspheres product was the first FDA-approved SGA long-acting IM formulation, and paliperidone palmitate was the first SGA depot formulation that could be administered at an interval of every 4 weeks. PP3M is the first depot antipsychotic that can be administered on a quarterly schedule. Overall, risperidone and paliperidone are well-tolerated SGA agents with efficacy comparable to that of most other agents in their class.

# CHAPTER 29

## Aripiprazole and Brexpiprazole

Rolando Gonzalez, M.D.

Martin T. Strassnig, M.D.

---

### History and Discovery

---

In this chapter, we review the preclinical and clinical pharmacology of aripiprazole and brexpiprazole, two novel atypical (second-generation) antipsychotics. Aripiprazole is a dihydroquinolinone antipsychotic agent. Chemically, it is unrelated to phenothiazines, butyrophenones, or thienobenzodiazepines. Pharmacologically, it exhibits a novel mechanism of action, combining partial agonist activity at dopamine type 2 ( $D_2$ ), dopamine type 3 ( $D_3$ ), and serotonin type 1A ( $5-HT_{1A}$ ) receptors with antagonist activity at serotonin type 2A ( $5-HT_{2A}$ ) and  $D_2$  receptors ([Burris et al. 2002](#); [Jordan et al. 2002](#)). Aripiprazole represents a significant innovation, following the

introduction of typical (first-generation) and atypical antipsychotics, in the pharmacology of therapeutic agents for psychotic disorders.

Brexpiprazole has been developed with a goal for further stabilization of dopaminergic transmission, more specifically regarding an optimal level of D<sub>2</sub> intrinsic activity. The pharmacological profile of brexpiprazole is similar to that of aripiprazole, including combined partial agonist activity at D<sub>2</sub>, D<sub>3</sub>, and 5-HT<sub>1A</sub> receptors with antagonist activity at 5-HT<sub>2A</sub> and D<sub>2</sub> receptors. However, brexpiprazole has lower intrinsic activity at D<sub>2</sub> receptors, high-potency partial agonism at 5-HT<sub>1A</sub> receptors, and stronger antagonism at 5-HT<sub>2A</sub> receptors ([Maeda et al. 2014b](#)).

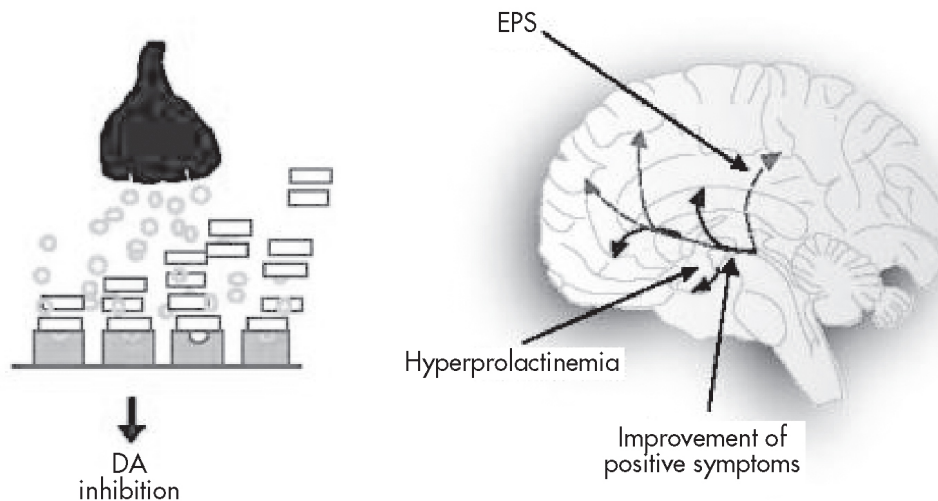

Although effective in alleviating psychotic symptoms and preventing their recurrence, the typical agents are ineffective in up to 40% of patients with schizophrenia, lack efficacy against the negative symptoms and cognitive deficits of schizophrenia, and are associated with a considerable burden of extrapyramidal side effects (EPS).

The atypical antipsychotics are partially effective against negative as well as positive symptoms and are associated with fewer EPS compared with the conventional antipsychotics. Nevertheless, individual atypical agents are associated with side effects such as weight gain and other metabolic abnormalities, hyperprolactinemia, QTc prolongation, and alterations in glucose and lipid levels ([Allison et al. 1999](#); [Glassman and Bigger 2001](#); [Koro et al. 2002a, 2002b](#); [McIntyre et al. 2001](#)).

The development of aripiprazole was guided by prevailing hypotheses of the etiology of schizophrenia. The dopamine hypothesis ([Seeman and Niznik 1990](#)) proposes that

abnormalities in dopaminergic neurotransmission in the brain cause the symptoms of schizophrenia and suggests that schizophrenia involves a biphasic disturbance in dopaminergic pathways (Davis et al. 1991; Pycock et al. 1980; Weinberger 1987). Underactivity of the mesocortical dopaminergic pathway leads to hypodopaminergic activity in the frontal cortex, whereas overactivity in the mesolimbic pathway causes increased dopaminergic neurotransmission. The latter is presumed to cause positive or psychotic symptoms, while the former is believed to underlie negative symptoms and cognitive impairment. Another influential hypothesis suggests that the activity of dopaminergic pathways is modulated by serotonergic neurons. In the striatum, serotonin (5-hydroxytryptamine; 5-HT) release inhibits dopamine, while in the frontal cortex it has a modulatory effect on pyramidal neurons and can affect glutamate release.

Most typical and atypical antipsychotic agents behave as full D<sub>2</sub> receptor antagonists. Their actions in the mesolimbic pathway would therefore be expected to benefit patients with schizophrenia by reducing positive symptoms. D<sub>2</sub> receptor antagonism in the other dopaminergic pathways, however, would be expected to cause unwanted side effects, including exacerbation of negative symptoms (mesocortical pathways), EPS and tardive dyskinesia (nigrostriatal tract), and hyperprolactinemia (tuberoinfundibular pathway) (Figure 29-1).

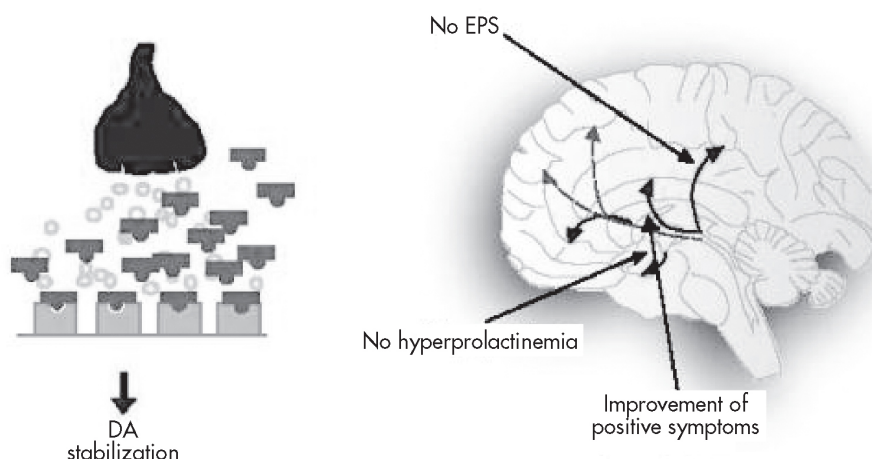

**FIGURE 29-1.** Conventional dopamine (DA) antagonist activity: effect on positive symptoms, extrapyramidal side effects (EPS), and prolactin levels.

The serotonin hypothesis may explain why the atypical agents, which have antagonist activity at 5-HT<sub>2A</sub> receptors, are associated with fewer EPS and do not exacerbate (and, in fact, partially alleviate) negative symptoms and cognitive impairment (Leysen et al. 1993; Millan 2000; Rao and Möller 1994; Richelson 1999).

On the basis of aripiprazole's pharmacodynamic profile—partial agonist activity (rather than full antagonist activity) at both dopaminergic (D<sub>2</sub>; Burris et al. 2002) and serotonergic (5-HT<sub>1A</sub>; Jordan et al. 2002) receptors, and full antagonist activity at 5-HT<sub>2A</sub> receptors (McQuade et al. 2002)—it was anticipated that aripiprazole treatment would be associated with a reduced burden of unwanted D<sub>2</sub> antagonist activity in the mesocortical, nigrostriatal, and tuberoinfundibular pathways—the activity associated with

some of the side effects of typical and atypical antipsychotic agents ([Figure 29-2](#)).

---

**FIGURE 29-2.** Dopamine (DA) partial agonist activity: effect on positive symptoms, extrapyramidal side effects (EPS), and prolactin levels.

Brexpiprazole's reduced intrinsic activity at  $D_2$  receptors and stronger antagonism at  $5-HT_{2A}$  receptors relative to aripiprazole suggest a lower potential to induce  $D_2$  partial agonist-mediated effects (i.e., akathisia, insomnia, nausea, and restlessness) and  $D_2$  antagonist effects (i.e., dystonias, tardive dyskinesia, and hyperprolactinemia) ([Fleischhacker 2005](#); [Maeda et al. 2014a](#)).

---

## Structure-Activity Relations and Pharmacological Profile

---

# Aripiprazole

Aripiprazole—7-{ 4-(4-[2,3-dichlorophenyl]-1-piperazinyl)butoxy} -3,4-dihydrocarbostyryl, a dihydroquinolinone ([Figure 29-3](#))—exhibits potent partial agonist activity at D<sub>2</sub> ([Burris et al. 2002](#)) and 5-HT<sub>1A</sub> ([Jordan et al. 2002](#)) receptors, together with potent antagonist activity at 5-HT<sub>2A</sub> receptors. It also has high affinity for D<sub>3</sub> receptors; moderate affinity for dopamine<sub>4</sub> (D<sub>4</sub>), serotonin<sub>2C</sub> (5-HT<sub>2C</sub>), serotonin<sub>7</sub> (5-HT<sub>7</sub>), α<sub>1</sub>-adrenergic, and histamine<sub>1</sub> (H<sub>1</sub>) receptors and the serotonin transporter (SERT); and negligible affinity for cholinergic muscarinic receptors ([Table 29-1](#)). The active metabolite of aripiprazole, dehydroaripiprazole, exhibits a similar affinity at D<sub>2</sub> receptors and has not been shown to have a pharmacological profile that is clinically significantly different from that of the parent compound.

## Brexpiprazole

Brexpiprazole—7-{ 4-[4-(1-benzothiophen-4-yl)piperazin-1-yl]butoxy} quinolin-2(1H)-one (Figure 29-4)—exhibits potent partial agonist properties at 5-HT<sub>1A</sub>, D<sub>2</sub>, and D<sub>3</sub> receptors. This is combined with potent antagonist activity at 5-HT<sub>2A</sub> receptors and α<sub>1B</sub>/α<sub>2C</sub> adrenoceptors. It also displays antagonistic properties at serotonin<sub>2B</sub> (5-HT<sub>2B</sub>) and serotonin<sub>7A</sub> (5-HT<sub>7A</sub>) receptors and moderate-potency antagonism at H<sub>1</sub> receptors. Brexpiprazole has negligible

affinity for cholinergic muscarinic receptors (Table 29-2) (Maeda et al. 2014a; Otsuka Pharmaceutical 2015).

## Pharmacokinetics and Disposition

---

### Aripiprazole

Aripiprazole is available for oral administration as tablets in strengths of 2, 5, 10, 15, 20, and 30 mg. The effective dosage range is 10–30 mg/day for schizophrenia patients and 15–30 mg/day for bipolar I disorder patients. For adjunctive treatment of major depressive disorder (MDD) and irritability associated with autism spectrum disorder, the recommended dosage range is 2–15 mg/day. For Tourette's disorder, body weight-based dosing of 2–10 mg/day for patients weighing less than 50 kg and 2–20 mg/day for patients weighing 50 kg or more is indicated. Aripiprazole is taken once daily with or without food and is well absorbed after oral administration, with peak plasma concentrations occurring within 3–5 hours. Absolute oral bioavailability is 87%. In plasma, aripiprazole and its major metabolite, dehydroaripiprazole, are both more than 99% bound to proteins, primarily albumin. Aripiprazole is extensively distributed outside the vascular system, and human studies demonstrating dose-dependent occupancy of D<sub>2</sub> receptors have confirmed that aripiprazole penetrates the brain. Elimination half-lives for aripiprazole and dehydroaripiprazole are 75 hours and 94 hours, respectively ([Otsuka Pharmaceutical 2016a](#)).

Of note, several aripiprazole formulations were withdrawn from the market by the manufacturer in 2015 for reasons unrelated to efficacy, safety, or tolerability. Discontinued formulations include the aripiprazole oral disintegrating tablet at 10-mg and 15-mg strengths, the oral solution, and the short-acting intramuscular injection.

In February 2013, the U.S. Food and Drug Administration (FDA) approved a long-acting injectable formulation of aripiprazole for the treatment of schizophrenia. The effective dosage range is 300–400 mg once monthly. It is recommended that oral aripiprazole supplementation (at

10–20 mg/day) or an alternative antipsychotic be continued for 2 weeks after the first administered injection of long-acting aripiprazole. The aripiprazole depot formulation consists of a lyophilized powder of unmodified aripiprazole. The depot formulation is reconstituted in water and injected into the gluteal muscle. The median peak plasma concentration is reached after 5–7 days. The mean terminal half-lives of the 300-mg and 400-mg doses are 29.9 and 46.5 days, respectively. Steady-state plasma concentration is attained after the fourth dose ([Otsuka Pharmaceutical 2016b](#)). The aripiprazole once-monthly dose of 400 mg with supplemental oral aripiprazole 10 mg/day for the first 2 weeks produces a pharmacokinetic profile consistent with multiple daily dosing of aripiprazole 10–30 mg, with a maximum plasma concentration comparable to the 30 mg/day dosage and a minimum plasma concentration comparable to the 10 mg/day dosage ([Mallikaarjun et al. 2013](#)).

In October 2015, the FDA approved aripiprazole lauroxil, a second long-acting injectable formulation of aripiprazole, for the treatment of schizophrenia. The effective dosages (441 mg, 662 mg, and 882 mg once monthly) correlate with oral aripiprazole dosages of 10 mg, 20 mg, and 30 mg/day, respectively. Aripiprazole lauroxil 882 mg may be administered at a dosing interval up to 6 weeks. The recommended period of oral aripiprazole supplementation is 3 weeks after the first administered injection.

Aripiprazole lauroxil, a prodrug of aripiprazole, initially undergoes enzyme-mediated hydrolysis to *N*-hydroxymethyl aripiprazole and then undergoes water-mediated hydrolysis to aripiprazole, the active form. After a single intramuscular injection, aripiprazole appears in systemic circulation within 5–6 days. Aripiprazole reaches steady state after

four consecutive monthly injections. Mean terminal half-life ranges from 29.2 to 34.9 days ([Alkermes 2015](#)).

Aripiprazole is metabolized primarily in the liver. Two hepatic cytochrome P450 (CYP) enzymes, 2D6 and 3A4, catalyze its dehydrogenation to dehydroaripiprazole. Therefore, coadministration of aripiprazole with inducers or inhibitors of these CYP enzymes may require dosage adjustment. The active metabolite accounts for 40% of drug exposure, but the predominant circulating moiety is the parent drug. Aripiprazole does not undergo direct glucuronidation and is not a substrate for the following CYP enzymes: 1A1, 1A2, 2A6, 2B6, 2C8, 2C9, 2C19, and 2E1. Interactions with inhibitors or inducers of these enzymes, or with chemicals related to cigarette smoke, are therefore unlikely to occur.

## Brexpiprazole

Brexpiprazole is available for oral administration as tablets in strengths of 0.25, 0.5, 1, 2, and 3 mg. The effective dosage range is 2–4 mg/day for treatment of schizophrenia and 1–3 mg/day for adjunctive treatment of MDD. Brexpiprazole is taken once daily with or without food and is well absorbed after oral administration, with peak plasma concentrations occurring within 4 hours. Absolute oral bioavailability is 95%. Brexpiprazole is highly bound to serum albumin and  $\alpha_1$ -acid glycoprotein (>99%). Elimination half-lives for brexpiprazole and DM-3411, its major metabolite, are 91 hours and 86 hours, respectively ([Otsuka Pharmaceutical 2015](#)).

Brexpiprazole is metabolized primarily through the liver by CYP enzymes 2D6 and 3A4. Therefore, coadministration

of brexpiprazole with inducers or inhibitors of these CYP enzymes may require dosage adjustment. At steady state (which is reached in 10–12 days), the inactive metabolite DM-3411 represents 23%–48% of brexpiprazole AUC (area under the time–concentration curve) in plasma ([Otsuka Pharmaceutical 2015](#)).

---

## Mechanism of Action

---

Aripiprazole and brexpiprazole both have partial agonist activity at D<sub>2</sub> receptors. The activity of aripiprazole and brexpiprazole at D<sub>2</sub> receptors has been studied in animal models of schizophrenia ([Kikuchi et al. 1995](#); [Maeda et al. 2014b](#)). In the intact rat with repetitive stereotyped behavior (stereotypy) induced by apomorphine, aripiprazole and brexpiprazole inhibit stereotypy and locomotion ([Kikuchi et al. 1995](#); [Maeda et al. 2014a](#)). These agents may therefore be expected to inhibit hyperdopaminergic activity in the mesolimbic pathway of patients with schizophrenia, thereby (like other available agents) exerting antipsychotic action against the positive symptoms of schizophrenia. On the other hand, in animal models of hypodopaminergic activity, such as the reserpinized rat, aripiprazole and brexpiprazole have D<sub>2</sub> receptor agonist activity ([Maeda et al. 2014b](#)). Because aripiprazole and brexpiprazole may exert either D<sub>2</sub> antagonist activity under hyperdopaminergic conditions or D<sub>2</sub> agonist activity under hypodopaminergic conditions, they may be less likely than other antipsychotics to cause excessive D<sub>2</sub> receptor antagonism. In preclinical studies, brexpiprazole showed lower intrinsic activity at D<sub>2</sub>

receptors, which suggests a reduced propensity to cause D<sub>2</sub> agonist-associated side effects such as nausea, insomnia, and akathisia ([Maeda et al. 2014a, 2014b](#)). It is possible that this lower activity may diminish the effects of excess D<sub>2</sub> receptor antagonism, including EPS. No comparative clinical trials of aripiprazole and brexpiprazole have yet been conducted.

Both aripiprazole and brexpiprazole may offer further therapeutic benefits through modulation of central serotonergic pathways. Preclinical studies showed that aripiprazole and brexpiprazole have antagonist activity at 5-HT<sub>2A</sub> receptors ([Maeda et al. 2014b; McQuade et al. 2002](#)), a characteristic that has been associated with reductions in EPS ([Meltzer 1999](#)) and in negative symptoms. In vitro studies also have shown that both aripiprazole and brexpiprazole have partial agonist activity at 5-HT<sub>1A</sub> receptors ([Jordan et al. 2002; Maeda et al. 2014b](#)), a feature that has been associated with improvement in negative, cognitive, depressive, and anxiety symptoms ([Millan 2000](#)).

The side effects of nausea/vomiting may be explained by the dopamine agonist effects of aripiprazole and brexpiprazole, whereas orthostatic hypotension and mild sedation/weight gain are likely related to these agents' antagonist activity at  $\alpha_1$ -adrenergic and H<sub>1</sub> receptors, respectively.

Aripiprazole lauroxil is a prodrug of aripiprazole. It initially undergoes enzyme-mediated hydrolysis to *N*-hydroxymethyl aripiprazole and then undergoes water-mediated hydrolysis to aripiprazole, the active form ([Alkermes 2015](#)).

---

# Indications and Efficacy

---

## Aripiprazole

In the United States, aripiprazole is approved by the FDA for the following indications: treatment of schizophrenia in adults and in adolescents ages 13–17 years; acute treatment of manic or mixed episodes associated with bipolar I disorder as monotherapy and as an adjunct to lithium or valproate in adults and pediatric patients ages 10–17 years; maintenance treatment of manic or mixed episodes associated with bipolar I disorder as monotherapy and as an adjunct to lithium or valproate in adults; use as an adjunct to antidepressant treatment in adults with MDD who have had an inadequate response to antidepressant therapy; treatment of irritability associated with autism spectrum disorder in pediatric patients ages 6–17 years; and treatment of Tourette’s disorder in pediatric patients ages 6–18 years. Additionally, intramuscular aripiprazole injection is approved for the acute treatment of agitation associated with schizophrenia or bipolar disorder (manic or mixed) in adults, and currently is available in two formulations for long-acting injectable depot maintenance and relapse management of schizophrenia in adults. The previously available formulations Abilify Discmelt orally disintegrating tablet (10 mg and 15 mg), Abilify oral solution (1 mg/mL), and Abilify short-acting intramuscular injection (9.75 mg/1.3 mL) were voluntarily withdrawn from the U.S. market in 2015.

## Schizophrenia

The efficacy of aripiprazole in the treatment of an acute symptom relapse in schizophrenia was demonstrated in four short-term (4-week) double-blind, placebo-controlled studies. Among these was a pivotal Phase III parallel-group multicenter study with four treatment arms comparing aripiprazole (15 or 30 mg/day) with placebo ([Kane et al. 2002](#)). Aripiprazole at either dosage produced statistically significant improvements from baseline on standard psychometric scales by week 2. This trial suggested that at daily dosages of 15 mg and 30 mg, aripiprazole provides effective symptom control in patients experiencing an acute exacerbation of schizophrenia symptoms.

In another short-term multicenter Phase III study involving acute symptom relapse in schizophrenia or schizoaffective disorder ([Potkin et al. 2003](#)), patients were randomly assigned to receive aripiprazole 20 mg/day, aripiprazole 30 mg/day, risperidone 6 mg/day, or placebo for 4 weeks. Compared with placebo, aripiprazole (at both dosages) and risperidone produced statistically significant improvements in scores on standard scales designed to measure antipsychotic efficacy.

The antipsychotic efficacy of aripiprazole in acute symptom relapse in schizophrenia was also demonstrated in two Phase II dose-ranging studies. Patients were randomly assigned to receive aripiprazole 2 mg, 10 mg, or 30 mg/day or haloperidol 10 mg/day ([Daniel et al. 2000](#)). All three dosages of aripiprazole produced improvements from baseline on efficacy measures, and the 30-mg/day dosage produced statistically significant improvement compared with placebo on all illness scores. Similarly, in a Phase II dosage titration study, aripiprazole 5–30 mg/day was superior to placebo in improving Brief Psychiatric Rating Scale (BPRS) Total, BPRS Core, Clinical Global Impression–

Severity (CGI-S), and Positive and Negative Syndrome Scale (PANSS)-Total scores ([Petrie et al. 1997](#)).

Results from the three 4-week fixed-dosage studies discussed above were pooled for analysis with those from an additional 6-week placebo-controlled, fixed-dosage study of aripiprazole at 10 mg, 15 mg, or 20 mg/day ([Lieberman et al. 2002](#)). The pooled analysis, involving 898 patients randomly assigned to receive aripiprazole, showed that at all investigated dosages greater than 2 mg/day, aripiprazole exhibited antipsychotic efficacy superior to that of placebo. Onset of effect was rapid, with improvement on psychometric scores detectable within 1 week of starting treatment. These pooled efficacy results demonstrate that dosages of 10–30 mg/day represent an effective therapeutic range for aripiprazole treatment.

Two long-term double-blind, randomized controlled multicenter trials yielded further confirmation of aripiprazole's efficacy. A 26-week placebo-controlled study in patients with chronic stable schizophrenia investigated the efficacy of aripiprazole 15 mg/day in relapse prevention ([Pigott et al. 2003](#)). Aripiprazole treatment significantly increased the time to relapse and resulted in significantly fewer relapses at endpoint compared with placebo (34% vs. 57%). From week 6 of therapy, PANSS-Total and PANSS-Positive subscale scores were significantly more improved with aripiprazole than with placebo.

In a 52-week study ([Kasper et al. 2003](#)), patients with schizophrenia who were experiencing an acute symptom relapse were randomly assigned to receive aripiprazole 30 mg/day or haloperidol 10 mg/day. Significantly more aripiprazole-treated patients than haloperidol-treated patients were still taking the medication and responding to treatment at weeks 8, 26, and 52. Both treatments

produced sustained improvements from baseline on PANSS-Total and PANSS-Positive subscale scores. However, aripiprazole produced significantly greater improvements in negative and depressive symptoms at weeks 26 and 52 and was associated with significantly lower scores on all EPS assessments compared with haloperidol.

The efficacy of aripiprazole monotherapy in antipsychotic-resistant schizophrenia was evaluated in a 6-week double-blind, randomized trial in patients whose symptoms had not improved during a prospective 4- to 6-week open trial with either olanzapine or risperidone ([Kane et al. 2007](#)). Subjects were randomly assigned to receive aripiprazole (15–30 mg/day) or perphenazine (8–64 mg/day). After 6 weeks, there was no statistical difference between the two groups on efficacy measures. However, compared with aripiprazole, perphenazine was associated with higher rates of EPS and serum prolactin elevations.

The efficacy of aripiprazole in the treatment of schizophrenia in pediatric patients (ages 13–17 years) was evaluated in a 6-week placebo-controlled outpatient trial comparing two fixed daily dosages of aripiprazole (10 mg or 30 mg) with placebo ([Findling et al. 2008](#)). Both aripiprazole dosages demonstrated statistically significant differences from placebo in reductions in PANSS-Total score; the 30-mg/day dosage was not shown to be more efficacious than the 10-mg/day dosage. Adverse events occurring in more than 5% of either aripiprazole group and with a combined incidence at least twice the rate for placebo were EPS, somnolence, and tremor. Mean body weight changes were –0.8, 0.0, and +0.2 kg for placebo, aripiprazole 10 mg/day, and aripiprazole 30 mg/day, respectively.

Two studies have investigated the efficacy of aripiprazole long-acting depot injection in the prevention of relapse in schizophrenia. In the first investigation, a 52-week randomized, placebo-controlled, long-term multicenter maintenance study, subjects requiring chronic treatment with an antipsychotic entered an oral aripiprazole stabilization phase followed by an intramuscular depot conversion and stabilization phase. Those patients meeting stabilization criteria for 12 consecutive weeks were then randomly assigned to receive aripiprazole 400-mg long-acting depot or placebo depot for the 52-week double-blind maintenance phase of the study. The primary outcome measure was time to relapse, defined as meeting any or all of the following criteria at any time during the maintenance phase: 1) clinical worsening (defined as Clinical Global Impression-Improvement [CGI-I] score  $\geq 5$  plus increase in any core PANSS items), 2) hospitalization, 3) risk of suicide, or 4) violent behavior. The aripiprazole group showed a significantly lower rate of relapse compared with the placebo group (9.6% vs. 36.8%, respectively) ([Kane et al. 2012](#)). The second investigation was a 38-week double-blind noninferiority study that compared relapse rates for aripiprazole once-monthly 400-mg depot injection, oral aripiprazole (10–30 mg/day), and aripiprazole once-monthly 50-mg depot injection, using criteria similar to those used in the Kane et al. study discussed above. There was no significant difference in rate of relapse with the once-monthly 400-mg depot formulation (7.12%) versus the oral formulation (10–30 mg/day), and both were significantly superior to the 50-mg depot formulation (21.8%;  $P < 0.0001$ ) ([Fleischhacker et al. 2014](#)).

One 12-week randomized, double-blind, placebo-controlled Phase III multicenter trial evaluated the efficacy

of aripiprazole once-monthly injection for the management of acute exacerbations in chronic schizophrenia. Patients were randomly assigned to either the aripiprazole once-monthly 400-mg group with concomitant oral aripiprazole (mean daily dosage=12.8 mg) for 2 weeks ( $n=168$ ) or the placebo group ( $n=172$ ). The aripiprazole group showed sustained improvements in PANSS-Total scores, PANSS-Positive and -Negative subscale scores, and CGI-I scores, with improvements apparent within the first week of administration ([Kane et al. 2014](#)).

An open-label mirror-image multicenter study in a naturalistic community setting ([Kane et al. 2013](#)) compared total psychiatric hospitalization rates in 183 patients (18–65 years) who had previously been treated with oral antipsychotics (retrospective phase) and who were then switched to the aripiprazole once-monthly depot formulation for 6 months (prospective phase). The rate of hospitalization for the 6-month prospective phase (14.2%) was found to be lower than the rate for the 6-month retrospective oral antipsychotic period (41.5%;  $P<0.0001$ ). Additionally, the all-cause discontinuation rate for the prospective phase was high (44.8%), with 26 patients discontinuing because of adverse events including “psychiatric disorders” (e.g., worsening of psychoses, increased paranoia, agitation, anxiety, decreased self-care; 20 patients) and “nervous-system disorders” (akathisia; 2 patients). For all patients receiving at least one dose of aripiprazole once monthly ( $n=181$ ), the most common treatment-emergent adverse events (occurring in  $\geq 5\%$  of patients) were psychotic disorder (7.7%), akathisia (7.2%), and insomnia (7.2%) ([Kane et al. 2013](#)).

[Meltzer et al. \(2015\)](#) conducted a 12-week double-blind, placebo-controlled multicenter study comparing once-

monthly administration of aripiprazole lauroxil 441 mg or 882 mg versus placebo for 12 weeks. Statistically significant improvement was observed on the PANSS-Total score from baseline to day 85 in both medication groups, with placebo-adjusted differences of  $-10.9$  ( $P < 0.001$ ) and  $-11.9$  ( $P < 0.001$ ) for aripiprazole lauroxil 441 mg and 882 mg, respectively.

## **Bipolar Disorder**

The efficacy of aripiprazole in the treatment of acute manic episodes was established in two 3-week placebo-controlled trials in hospitalized patients whose symptoms met DSM-IV ([American Psychiatric Association 1994](#)) criteria for bipolar I disorder with manic or mixed episodes ([Keck et al. 2003](#); [Sachs et al. 2006](#)). Aripiprazole was superior to placebo in reducing the Young Mania Rating Scale (YMRS) Total score and the Clinical Global Impression-Bipolar (CGI-BP) Severity of Illness score. In a third large randomized, double-blind trial ([Vieta et al. 2005](#)), aripiprazole was compared with haloperidol in the treatment of acute bipolar mania over a 12-week period. Significantly more patients remained in treatment and were classified as responders ( $>50\%$  reduction in YMRS score from baseline) at week 12 in the aripiprazole group (49.7%) than in the haloperidol group (28.4%). EPS adverse events were more frequent with haloperidol than with aripiprazole (62.7% vs. 24.0%).

The efficacy of adjunctive aripiprazole with concomitant lithium or valproate in the treatment of manic or mixed episodes was established in a 6-week placebo-controlled study with a 2-week lead-in mood stabilizer monotherapy phase in adult patients who met DSM-IV criteria for bipolar I disorder ([Vieta et al. 2008](#)). Adjunctive aripiprazole starting at 15 mg/day with concomitant lithium or valproate

(in a therapeutic range of 0.6–1.0 mEq/L or 50–125 µg/mL, respectively) was found to be superior to lithium or valproate with adjunctive placebo on the basis of reductions in YMRS Total scores and CGI-BP Severity of Illness scores.

Aripiprazole monotherapy was evaluated in the treatment of nonpsychotic depressive episodes associated with bipolar I disorder. The results of two identically designed 8-week randomized, double-blind, placebo-controlled multicenter studies were reported by [Thase et al. \(2008\)](#). The primary outcome measure was mean change from baseline to week 8 (last observation carried forward [LOCF]) in the Montgomery-Åsberg Depression Rating Scale (MADRS) Total score. Although statistically significant differences were observed during weeks 1–6, there were no statistically significant differences in change in MADRS Total score between aripiprazole and placebo at week 8 in either study.

To evaluate the long-term effectiveness of aripiprazole in delaying relapse in bipolar I disorder, a trial was conducted in patients whose symptoms met DSM-IV criteria for bipolar I disorder with a recent manic or mixed episode ([Keck et al. 2006](#)). Patients whose condition had been stabilized while taking open-label aripiprazole and who had maintained a clinical response for at least 6 weeks were randomly assigned to receive aripiprazole or placebo for the 26-week, double-blind phase. Aripiprazole-treated patients had significantly fewer relapses than placebo-treated patients (25% vs. 43%). Aripiprazole was superior to placebo in delaying the time to manic relapse but did not differ from placebo in delaying time to depressive relapse. Significant weight gain ( $\geq 7\%$  increase from baseline) was seen in 13% of the aripiprazole patients and none of the placebo patients.

The efficacy of aripiprazole in the treatment of bipolar I disorder in pediatric patients (ages 10–17 years) was evaluated in two studies. The first study was a 4-week double-blind, placebo-controlled trial of outpatients whose symptoms met DSM-IV criteria for bipolar I disorder manic or mixed episodes with or without psychotic features. The trial compared two fixed daily dosages of aripiprazole (10 mg or 30 mg). Both dosages of aripiprazole were superior to placebo as measured by change from baseline to week 4 on the YMRS Total score ([Otsuka Pharmaceutical 2016a](#)). The second study was a 30-week randomized, placebo-controlled study comparing fixed daily dosages of aripiprazole (10 mg and 30 mg) with placebo in the treatment of adolescent bipolar disorder ([Findling et al. 2013](#)). Two hundred ten youths (ages 10–17 years) with bipolar I disorder (manic or mixed) with or without psychotic features were randomly assigned to receive oral aripiprazole 10 mg/day, oral aripiprazole 30 mg/day, or placebo. Both dosages of aripiprazole were superior to placebo; at week 30, aripiprazole-treated patients demonstrated significantly greater improvement on YMRS Total scores compared with placebo-treated patients.

## **Acute Agitation**

The efficacy of the injectable formulation of aripiprazole in controlling acute agitation was evaluated in three short-term (24-hour) randomized, double-blind, placebo-controlled studies in patients with schizophrenia ([Andrezina et al. 2006](#); [Tran-Johnson et al. 2007](#)) and patients with bipolar disorder (manic or mixed) ([Zimbroff et al. 2007](#)). Aripiprazole injection was statistically superior to placebo ( $P<0.05$ ) in all three studies, as measured by PANSS-Excited Component (PANSS-EC) scores. In the two studies

in agitated patients with schizophrenia, injectable aripiprazole and intramuscular haloperidol were both superior to placebo. In the study in agitated patients with bipolar I disorder, aripiprazole injection and lorazepam injection were both superior to placebo.

## **Adjunctive Treatment of Major Depressive Disorder**

The efficacy of aripiprazole in the adjunctive treatment of MDD was demonstrated in three short-term (6-week) placebo-controlled trials ([Berman et al. 2007, 2009](#); [Marcus et al. 2008](#)). During prospective antidepressant treatment, patients received one of several antidepressants (escitalopram, fluoxetine, paroxetine controlled release, sertraline, or venlafaxine extended release), each with single-blind adjunctive placebo. Patients with incomplete response continued taking the antidepressant and were randomly assigned to receive double-blind adjunctive placebo or adjunctive aripiprazole (2–15 mg/day with the potent CYP2D6 inhibitor fluoxetine or paroxetine; 2–20 mg/day with all other antidepressants). In all three trials, the mean change in MADRS Total score was significantly greater with adjunctive aripiprazole than with adjunctive placebo. Akathisia and restlessness were significantly more frequent with adjunctive aripiprazole than with adjunctive placebo.

[Fava et al. \(2012\)](#) evaluated the efficacy of low-dosage aripiprazole added to antidepressant therapy in patients with MDD who had experienced an inadequate response to prior antidepressant treatment. Two hundred twenty-five patients were randomly assigned to receive adjunctive treatment with aripiprazole 2 mg/day or placebo. The

pooled, weighted response difference between aripiprazole 2 mg/day and placebo was 5.6% ( $P=0.18$ ; not significant [NS]); the difference on the MADRS was  $-1.51$  ( $P=0.065$ ; NS). Of note, there was no difference in rates of akathisia with low-dosage aripiprazole compared with placebo. Thus, a reasonable initial therapeutic approach may be to try a low-dosage (2 mg/day) augmentation of aripiprazole, in view of its better tolerability, and to increase the dosage to 5 mg/day, and if necessary to 10 or 15 mg/day, in the face of continued nonresponse, given that the efficacy of the higher dosage range was supported by robust evidence in three previous positive studies ([Fava et al. 2012](#)).

## **Irritability in Autism Spectrum Disorder**

The efficacy of aripiprazole in the treatment of irritability associated with DSM-IV autistic disorder was established in two 8-week placebo-controlled trials in children and adolescents (ages 6–17 years). Efficacy was evaluated with two assessment scales: the Aberrant Behavior Checklist (ABC) and the CGI-I scale. In the first trial ([Owen et al. 2009](#)), pediatric patients with DSM-IV autistic disorder received aripiprazole (2–15 mg/day, based on clinical response) or placebo. Patients who received aripiprazole (at a mean daily dosage of 8.6 mg at the end of the 8-week treatment) demonstrated significantly improved scores on the ABC-Irritability (ABC-I) subscale and on the CGI-I scale compared with patients who received placebo. In the other trial ([Marcus et al. 2009](#)), three fixed dosages of aripiprazole (5, 10, or 15 mg/day) were compared with placebo. All three dosages of aripiprazole were associated with significantly improved scores on the ABC-I subscale compared with placebo.

The efficacy and safety of aripiprazole in the long-term maintenance treatment of pediatric patients with irritability associated with DSM-IV autistic disorder were evaluated in a double-blind, randomized, placebo-controlled multicenter study in patients ages 6–17 years. After an initial phase in which single-blind aripiprazole was flexibly dosed (2–15 mg/day; average dosage of 9.0 mg/day) for 13–26 weeks to establish a stable response (defined as a  $\geq 25\%$  decrease on the ABC-I subscale and a rating of “much improved” or “very much improved” on the CGI-I scale), patients were randomly assigned to receive either aripiprazole ( $n=41$ , 2–15 mg/day) or placebo ( $n=44$ ) for 16 weeks or until relapse. The primary outcome measure was time from randomization to relapse. No statistically significant differences in time to relapse were seen between the drug and the placebo group ( $P=0.97$ , hazard ratio=0.57, number needed to treat=6) ([Findling et al. 2014](#)).

## **Tourette’s Disorder**

The efficacy of aripiprazole in children and adolescents with Tourette’s disorder was established in two short-term trials. In the first study, a double-blind, randomized, placebo-controlled, flexible-dose multicenter trial, patients with Tourette’s disorder ( $n=61$ ) ages 6–18 years were randomly assigned to receive either placebo or aripiprazole (2–20 mg/day) for 10 weeks. Aripiprazole-treated patients demonstrated significant reductions on Yale Global Tic Severity Scale scores compared with patients receiving placebo ( $-15.0$  [8.4] and  $-9.6$  [8.8], respectively;  $P=0.0196$ ) ([Yoo et al. 2013](#)). The mean change in phonic tic scores favored the aripiprazole group, but there was no difference in motor tic scores. Treatment-emergent adverse events were not statistically significantly different. The

mean dosage range was 11.0 mg/day ([Yoo et al. 2013](#)). In the second study, a Phase III randomized, double-blind, placebo-controlled multicenter trial in patients with a diagnosis of Tourette's disorder (ages 7–17 years), patients first underwent a 3- to 42-day washout period ([Sallee et al. 2014](#)). A total of 133 patients were then randomly assigned to receive low-dosage aripiprazole (5 mg/day if < 50 kg, 10 mg/day if ≥50 kg), high-dosage aripiprazole (10 mg/day if <50 kg, 20 mg/day if ≥50 kg), or placebo for 8 weeks. Both the low-dosage and high-dosage aripiprazole groups showed significant improvement in Yale Global Tic Severity Scale and CGI-Tourette's Syndrome Scale scores compared with the placebo group ([Sallee et al. 2014](#)).

## Off-Label Use

[De Deyn et al. \(2005\)](#) compared the efficacy, safety, and tolerability of aripiprazole versus placebo in patients with psychosis associated with Alzheimer's disease in a 10-week double-blind multicenter study. The initial aripiprazole dosage of 2 mg/day was titrated upward (to 5, 10, or 15 mg/day) according to efficacy and tolerability, and evaluations included the Neuropsychiatric Inventory (NPI) Psychosis subscale and the BPRS. Aripiprazole-treated patients showed significantly greater improvements from baseline in BPRS-Psychosis subscale and BPRS-Core subscale scores at endpoint compared with patients receiving placebo.

In another double-blind multicenter study ([Mintzer et al. 2007](#)), patients with psychosis associated with Alzheimer's disease were randomly assigned to receive either placebo or aripiprazole 2, 5, or 10 mg/day. The primary efficacy measure was mean change from baseline to week 10 on the Neuropsychiatric Inventory-Nursing Home (NPI-NH)

Psychosis subscale score. Aripiprazole 10 mg/day showed significantly greater improvements than placebo on all efficacy measures (NPI-NH Psychosis subscale, CGI-S, BPRS Total and Core, and Cohen-Mansfield Agitation Inventory [CMAI] scores). Aripiprazole 5 mg/day showed significant improvements versus placebo on BPRS and CMAI scores. Aripiprazole 2 mg/day was not efficacious. No antipsychotic is currently approved in the United States for treating the behavioral and psychotic symptoms that frequently accompany dementia, and all carry a bolded warning based on increased mortality observed in patients with dementia-related psychosis treated with these agents.

[Nickel et al. \(2006\)](#) conducted a double-blind, placebo-controlled study in individuals whose clinical presentation met DSM-III-R ([American Psychiatric Association 1987](#)) criteria for borderline personality disorder. Subjects were randomly assigned in a 1:1 ratio to receive either aripiprazole (15 mg/day) or placebo for 8 weeks. At endpoint, significant changes in scores on most scales of the Symptom Checklist-90—Revised (SCL-90-R), on the Hamilton Rating Scale for Depression (Ham-D), on the Hamilton Anxiety Scale (Ham-A), and on all subscales of the State-Trait Anger Expression Inventory were observed in subjects who received aripiprazole. The improvements observed at 8 weeks were maintained at 18-month follow-up ([Nickel et al. 2007](#)).

[Tiihonen et al. \(2007\)](#) conducted a study in which individuals whose symptoms met DSM-IV criteria for intravenous amphetamine dependence were randomly assigned to receive aripiprazole (15 mg/day), slow-release methylphenidate (54 mg/day), or placebo for 20 weeks. The study was terminated prematurely because of unexpected results in the interim analysis. Contrary to the hypothesized

result, patients who received aripiprazole treatment had significantly more amphetamine-positive urine samples than did patients in the placebo group, and patients who received methylphenidate had significantly fewer amphetamine-positive urine samples than patients who received placebo. Studies in subjects with cocaine use disorder are ongoing.

In a 12-week double-blind, placebo-controlled multicenter trial ([Anton et al. 2008](#)) evaluating the efficacy of aripiprazole in patients with DSM-IV alcohol dependence, aripiprazole did not differ from placebo on the study's primary efficacy measure, mean percentage of days abstinent.

## Brexpiprazole

Brexpiprazole is currently approved in the United States for schizophrenia and for use as an adjunct to antidepressant treatment in adults with MDD who have had an inadequate response to antidepressant therapy ([Otsuka Pharmaceutical 2015](#)).

### Schizophrenia

The efficacy of brexpiprazole in the treatment of acute symptom exacerbations in schizophrenia has been evaluated in two 6-week double-blind, placebo-controlled multicenter studies. In the first study, a Phase III multicenter trial (BEACON study), patients with acute schizophrenia were randomly assigned to receive aripiprazole (1 mg, 2 mg, or 4 mg/day) or placebo. Brexpiprazole 4 mg/day produced statistically significant reductions (treatment difference  $-6.47$ ;  $P=0.0022$ ) versus

placebo on the PANSS-Total score. Brexpiprazole dosages of 1 mg/day and 2 mg/day also produced numerical improvements versus placebo, although the degree of improvement was not statistically significant ( $P>0.05$ ) ([Kane et al. 2015](#)).

In another 6-week multicenter double-blind, placebo-controlled Phase III trial (VECTOR study), patients experiencing an acute schizophrenia relapse were randomly assigned to receive aripiprazole (0.25 mg, 2 mg, or 4 mg/day) or placebo. At 6 weeks, both the 2-mg/day and the 4-mg/day dosages of brexpiprazole had produced statistically significantly greater reductions on PANSS-Total scores compared with placebo (treatment difference  $-8.72$  [ $P<0.0001$ ] and  $-7.64$  [ $P=0.0006$ ] for 2 mg/day and 4 mg/day, respectively) ([Correll et al. 2015](#)).

## **Adjunctive Treatment of Major Depressive Disorder**

The efficacy of brexpiprazole in the adjunctive treatment of MDD has been demonstrated in two short-term randomized, double-blind Phase III studies. In the first study ([Thase et al. 2015b](#)), patients who had not responded to three prior trials with antidepressants entered an 8-week prospective period of open-label treatment with an antidepressant. Patients who showed inadequate response (defined as a score of  $\geq 14$  on the 17-item Ham-D [Ham-D-17];  $<50\%$  reduction from baseline on the Ham-D-17 and the MADRS Total score; and a CGI-I score of  $\geq 3$ ) were randomly assigned to receive double-blind antidepressant plus brexpiprazole (2 mg/day) or antidepressant plus placebo. Adjunctive brexpiprazole 2 mg/day produced statistically significant reductions on MADRS Total scores

versus adjunctive placebo (i.e., antidepressant monotherapy) per final protocol ( $-8.36$  vs.  $-5.15$ , respectively;  $P=0.0002$ ) ([Thase et al. 2015b](#)).

The second study ([Thase et al. 2015a](#)) also evaluated the efficacy and safety of brexpiprazole (1 mg and 3 mg/day) versus placebo in the adjunctive treatment of antidepressant-resistant MDD. The study's design also included an 8-week single-blind prospective treatment phase in which patients received one antidepressant. Patients who had an inadequate response (defined as a Ham-D-17 score  $\geq 14$ ;  $<50\%$  reduction from baseline on the Ham-D-17 Total score and the MADRS Total score; and a CGI score  $\geq 3$ ) were randomly assigned to receive double-blind antidepressant plus brexpiprazole (1 mg/day or 3 mg/day) or antidepressant plus placebo. The brexpiprazole 3 mg/day treatment group showed statistically significant improvement (assessed by mean reduction from baseline in MADRS Total score) versus the placebo group ( $-8.29$  vs.  $-6.33$ , respectively;  $P=0.0079$ ), whereas the numerical improvement in MADRS Total score was not statistically significant for brexpiprazole 1 mg/day versus placebo ( $-7.64$ ;  $P=0.0079$ ) ([Thase et al. 2015a](#)).

---

## Side Effects and Toxicology

---

### Aripiprazole

A pooled analysis of safety and tolerability data from the five short-term studies ([Marder et al. 2003](#); [Stock et al. 2002](#)) showed that aripiprazole treatment was well tolerated. The most commonly reported adverse events

with aripiprazole were headache, insomnia, agitation, and anxiety. The incidence of adverse events was similar in the aripiprazole and placebo groups. The adverse-event profile of aripiprazole did not vary according to patient characteristics of age, sex, and race/ethnicity, and no deaths were reported during the short-term studies. Data from the four fixed-dosage studies showed that somnolence was the only adverse event seen with aripiprazole that was possibly dose related. Objective rating scale assessments were used to measure changes in parkinsonian symptoms (Simpson-Angus Scale [SAS]), dyskinesias (Abnormal Involuntary Movement Scale [AIMS]), and akathisia (Barnes Akathisia Rating Scale [BARS]). SAS scores with aripiprazole did not differ significantly from those with placebo, whereas AIMS scores improved significantly from baseline with aripiprazole compared with placebo. Aripiprazole did not produce consistent dose-dependent changes in BARS scores. The rate of discontinuation due to adverse events was 7.3% ([Otsuka Pharmaceutical 2016a](#)). According to the product labeling for aripiprazole in the United States, treatment-emergent adverse events most commonly reported with aripiprazole (occurring in  $\geq 10\%$  of patients with an incidence greater than that with placebo) in short-term trials of patients with schizophrenia (up to 6 weeks) or bipolar disorder (up to 3 weeks), respectively, included headache (aripiprazole 30% vs. placebo 25%), anxiety (20% vs. 17%), insomnia (19% vs. 14%), nausea (16% vs. 12%), vomiting (12% vs. 6%), dizziness (11% vs. 8%), constipation (11% vs. 7%), dyspepsia (10% vs. 8%), and akathisia (10% vs. 4%). A 26-week trial in schizophrenia reported a similar adverse-event profile except for a higher incidence of tremor (aripiprazole 8% vs. placebo 2%).

The most frequently reported adverse events with aripiprazole injection were headache (aripiprazole 12% vs. placebo 7%), nausea (9% vs. 3%), dizziness (8% vs. 5%), and somnolence (7% vs. 4%). In the three aripiprazole injection trials, the drug's safety profile was comparable to that of placebo regarding the incidence of EPS, akathisia, or dystonia. The incidence of akathisia-related adverse events with aripiprazole injection was 2% (vs. 0% for placebo), while the incidence of dystonia with aripiprazole injection was less than 1% (vs. 0% for placebo). In addition, the incidence of QTc prolongation was also comparable between aripiprazole injection and placebo.

The most common adverse events reported for the aripiprazole long-acting injectable formulation in the [Kane et al. \(2012\)](#) 52-week trial were insomnia (aripiprazole 10% vs. placebo 9%), tremor (5.9% vs. 1.5%), headache (5.9% vs. 5.2%), and akathisia (5.6% vs. 6%). In the [Kane et al. \(2014\)](#) 12-week acute management of schizophrenia study, the most common adverse events were increased weight (aripiprazole 16.8% vs. placebo 7%), headache (14.4% vs. 16.3%), and akathisia (11.4% vs. 3.5%). There was no significant difference in rates of EPS other than akathisia between the 400-mg aripiprazole group and the placebo group. In a 24-week open-label parallel-arm study conducted by [Mallikaarjun et al. \(2013\)](#), the tolerability and safety of aripiprazole once monthly in schizophrenia were comparatively evaluated for dosages of 200 mg, 300 mg, and 400 mg. The most common adverse events were injection-site pain (aripiprazole 400 mg, 28.6%), tremor (aripiprazole 400 mg, 21.4%; aripiprazole 300 mg, 6.7%), and vomiting (aripiprazole 300 mg, 13.3%; aripiprazole 400 mg, 14.3%).

The most common adverse events in a 12-week Phase III trial of aripiprazole lauroxil in the treatment of acute exacerbations of schizophrenia were akathisia, headache, insomnia, and injection-site pain (occurring in >5% of patients). Akathisia occurred at twice the rate of placebo for aripiprazole lauroxil 882 mg and 441 mg (4.3%, 11.6%, and 11.5%, respectively) ([Meltzer et al. 2015](#)). The majority (>75%) of akathisia episodes occurred within 3 weeks of receiving the first injection.

Minimal changes in mean body weight were observed with aripiprazole treatment in short-term studies (pooled data +0.71 kg) ([Marder et al. 2003](#)) and in long-term studies (26-week: -1.26 kg; 52-week: +1.05 kg) ([Kasper et al. 2003](#); [Pigott et al. 2003](#)).

Olanzapine and aripiprazole were compared on their propensity to cause weight gain and other metabolic disturbances in a 26-week randomized, double-blind multicenter trial ([McQuade et al. 2004](#)). Statistically significant differences in mean weight change were observed between treatments beginning at week 1 and were sustained throughout the study. At week 26, there was a mean weight loss of 1.37 kg (3.04 lb) with aripiprazole compared with a mean weight gain of 4.23 kg (9.40 lb) with olanzapine among patients who continued with therapy ( $P<0.001$ ). Changes in fasting plasma levels of total cholesterol, high-density lipoprotein cholesterol, and triglycerides were significantly different in the two treatment groups, with worsening of the lipid profile among patients treated with olanzapine.

Aripiprazole treatment was not associated with increases in prolactin levels during either short- or long-term studies. (In fact, prolactin levels were shown to be slightly decreased by aripiprazole.)

Overall, aripiprazole treatment is associated with a low incidence of EPS (other than akathisia) and EPS-related symptoms and with minimal or no effects on weight gain, QTc interval, or circulating levels of cholesterol, glucose, and prolactin. Treatment with aripiprazole may reduce the burden of antipsychotic-associated side effects, thereby leading to improved patient adherence and decreased risks of acute relapse.

## Brexpiprazole

Overall, brexpiprazole has been well tolerated in the four short-term clinical trials conducted thus far, with lower rates of discontinuation due to adverse events compared with placebo. In pooled analyses for two trials of brexpiprazole in the adjunctive treatment of MDD, the rate of discontinuation due to adverse reactions for all dosages of brexpiprazole was 3%, compared with 1% for placebo ([Otsuka Pharmaceutical 2015](#)). In the two Phase III trials for brexpiprazole in acute schizophrenia, the overall rates of discontinuation due to adverse event were lower than those for placebo ([Correll et al. 2015](#); [Kane et al. 2015](#)).

The most common side effects varied per available studies. In one Phase III trial in acute schizophrenia, the most common adverse events for brexpiprazole were headache, agitation, and insomnia, with rates of akathisia lower than those with placebo but with a dose-dependent increase for brexpiprazole ([Correll et al. 2015](#)). Comparatively, the most common adverse event in another Phase III trial was akathisia for brexpiprazole 2 mg (4.4%) and 4 mg (7.2%) versus placebo (2.2%), with akathisia most commonly occurring within the first 3 weeks of treatment.

In two short-term trials for adjunctive use in MDD, pooled analysis showed that the most common adverse event was akathisia (8.6%) ([Citrome 2015](#)).

Pooled data from two short-term Phase III schizophrenia trials showed that 10% of brexpiprazole-treated patients had weight gains of 7% or greater from baseline during a 6-week trial, compared with 4.1% of patients receiving placebo. Similarly, the pooled data from both short-term MDD trials showed weight gain in the brexpiprazole group to be higher than that in the placebo group (6.7% vs. 1.9%), with the greatest increase being 1.6 kg for brexpiprazole 3 mg/day at 6 weeks ([Citrome 2015](#); [Otsuka Pharmaceutical 2015](#)).

Change in prolactin level was studied in all treatment trials. In one Phase III trial of brexpiprazole in schizophrenia, there was no statistically significant change in prolactin level ([Correll et al. 2015](#)). In a second Phase III short-term trial of brexpiprazole in schizophrenia, the incidence of potentially clinically relevant prolactin values (one to two times the upper limit of normal) was highest in the brexpiprazole 4-mg/day group (19.1%) versus the placebo group (13.9%) ([Kane et al. 2015](#)). In a short-term Phase III trial of brexpiprazole in the adjunctive treatment of MDD, 0.4% of patients receiving brexpiprazole 3 mg/day, compared with 1.4% of patients receiving placebo, had a prolactin level greater than three times the upper limit of normal ([Thase et al. 2015b](#)).

The incidence of EPS was evaluated in all four short-term treatment trials by means of the BARS and the SAS. The percentage of patients treated with brexpiprazole plus an antidepressant who showed a shift from normal to abnormal was greater versus placebo for both the BARS (4% vs. 0.6%) and the SAS (4% vs. 3%). Similarly, the

brexpiprazole group showed a greater shift from normal to abnormal versus placebo in both the BARS (2% vs. 1%) and the SAS (7% vs. 5%) in pooled data from both schizophrenia trials ([Otsuka Pharmaceutical 2015](#)).

With an overall minimal incidence of EPS beyond akathisia and minimal observed changes in QTc, lipid panel, and glucose panel values compared with placebo, brexpiprazole is another antipsychotic with a tolerable side-effect profile that may improve adherence long term ([Correll et al. 2015](#); [Kane et al. 2015](#); [Thase et al. 2015a, 2015b](#)).

---

## Drug-Drug Interactions

---

### Aripiprazole

Because aripiprazole is metabolized primarily by the hepatic CYP enzymes 2D6 and 3A4, it has the potential to interact with other substrates for these enzymes. Inducers of these enzymes may increase clearance and thereby reduce blood levels of aripiprazole, whereas inhibitors of CYP3A4 or CYP2D6 may inhibit elimination and thereby increase blood levels of aripiprazole. In vivo studies showed decreased levels of aripiprazole and dehydroaripiprazole in the plasma when aripiprazole was coadministered with carbamazepine, a CYP3A4 inducer. The aripiprazole dose should therefore be increased when the drug is administered concomitantly with carbamazepine. In vivo studies coadministering aripiprazole and ketoconazole (a CYP3A4 inhibitor) or quinidine (a CYP2D6 inhibitor) suggest that the aripiprazole dose should be reduced when

aripiprazole is administered with strong 3A4 or 2D6 inhibitors. Aripiprazole exhibits  $\alpha_1$ -adrenergic receptor antagonist activity and therefore may enhance the effects of certain antihypertensive agents.

## Brexpiprazole

Brexpiprazole is metabolized primarily by hepatic CYP enzymes 2D6 and 3A4; therefore, coadministration with inducers or inhibitors of these CYP enzymes requires dosage adjustments for brexpiprazole. In vivo studies showed increased levels of brexpiprazole when it was coadministered with ketoconazole (a CYP3A4 inhibitor) or quinidine (a CYP2D6 inhibitor), and it is therefore recommended that brexpiprazole dosages be reduced when brexpiprazole is coadministered with known CYP2D6 and CYP3A4 inhibitors. Plasma levels of brexpiprazole were decreased when the drug was coadministered with rifampin (a CYP3A4 inducer) during in vivo studies, and it is therefore recommended that brexpiprazole dosages be reduced when brexpiprazole is coadministered with known CYP3A4 inducers. Brexpiprazole has limited induction or inhibition of other CYP enzymes per multiple in vivo studies ([Otsuka Pharmaceutical 2015](#)).

---

## Conclusion

---

Aripiprazole was the first agent that was not a full D<sub>2</sub> receptor antagonist to show rapid and sustained antipsychotic activity, and it may be considered the first partial dopamine agonist combined with 5-HT-stabilizing

properties. Short-term and long-term clinical trials in adult and pediatric patients with schizophrenia and bipolar I disorder have demonstrated that aripiprazole combines sustained antipsychotic and mood-stabilizing efficacy with an excellent safety and tolerability profile. Additional augmentation trials have confirmed the utility of aripiprazole in alleviating depressive symptomatology in patients with MDD who have not achieved adequate symptom relief with antidepressants alone. The efficacy and safety of aripiprazole have also been established in child and adolescent populations for the management of irritability in autism spectrum disorders and Tourette's disorder. Aripiprazole is now also available in two different long-term depot injectable formulations for the management of schizophrenia in adults.

Brexpiprazole shares multiple similarities with aripiprazole, including partial dopamine agonism and 5-HT-stabilizing properties. However, brexpiprazole has lower intrinsic dopaminergic activity than does aripiprazole, which may indicate an even more favorable side-effect profile relative to the well-tolerated older drug. Several short-term clinical trials in adult patients with acute schizophrenia or with a lack of response to previous therapy for MDD have confirmed the efficacy and tolerability of this newly established atypical antipsychotic. A variety of clinical trials with brexpiprazole targeting different treatment populations, including head-to-head trials with other antipsychotics to further establish clinical efficacy, have been initiated or are ongoing.

In general, both aripiprazole and brexpiprazole are associated with low liability for EPS, QTc interval prolongation, prolactin elevation, weight gain, and disturbance of glucose or lipid metabolism. The

combination of efficacy, safety, and tolerability suggests that both aripiprazole and brexpiprazole represent important options for the acute treatment of schizophrenia as well as for the adjunctive treatment of MDD. Aripiprazole additionally represents an important treatment option for bipolar I disorder, irritability in autism spectrum disorder, and Tourette's disorder, and for long-term management of schizophrenia.

# CHAPTER 30

## Ziprasidone

John W. Newcomer, M.D.

Elise Fallucco, M.D.

Martin T. Strassnig, M.D.

---

### History and Discovery

---

Ziprasidone (CP-88059) is an atypical, or *second-generation*, antipsychotic agent that has activity for treating positive, negative, cognitive, and affective symptoms of schizophrenia and schizoaffective disorder and for treating mania and mixed states in bipolar disorder, with limited adverse extrapyramidal, sedative, anticholinergic, and cardiometabolic effects. First approved in 2001, this antipsychotic was initially part of a new drug application for the treatment of psychotic disorders submitted to the U.S Food and Drug Administration (FDA) in 1997. Because of concerns regarding an increase in the mean duration of the QT interval, an electrocardiographic measure of the ventricular depolarization and repolarization phases of

cardiac conduction, the application was not initially approved. Further studies, designed in collaboration with the FDA, quantified the limited extent of the QTc interval lengthening effect seen with ziprasidone compared with that seen with other agents in wide use; these studies established the safety of ziprasidone with respect to cardiac conduction and a benchmark for the approach to evaluating drug effects on the QT interval that has subsequently been applied to other agents evaluated by the FDA. Ziprasidone has received regulatory approval and is available in more than 92 countries.

---

## Pharmacological Profile

---

### Neuropharmacology and Receptor-Binding Profile

Ziprasidone, or 5-{2-[4-(1,2-benzisothiazol-3-yl)-1-piperazinyl]ethyl}-6-chloro-1,3-dihydro-2H-indol-2-one, is a novel benzisothiazolylpiperazine antipsychotic ([Figure 30-1](#)).

---

**FIGURE 30-1.** Chemical structure of ziprasidone.

## **Dopamine Type 2 and Serotonin Type 2A Receptor Activity**

Ziprasidone is a potent antagonist at dopamine type 2 ( $D_2$ ) receptors with inverse agonist activity at serotonin (5-hydroxytryptamine) type 2A ( $5-HT_{2A}$ ) receptors.  $D_2$  receptor antagonism is thought to be a key mechanism explaining efficacy for the treatment of psychotic symptoms ([Kapur and Remington 2001](#)); positron emission tomography (PET) studies have shown that clinical antipsychotic response to ziprasidone is predicted by occupancy of at least 60% of striatal  $D_2$  receptors.  $D_2$  receptor antagonism is also associated with potential liability for extrapyramidal side effects (EPS). However, ziprasidone also has inverse agonist activity at  $5-HT_{2A}$  receptors, an effect that can disinhibit dopamine neurotransmission in the nigrostriatal, mesocortical, and tuberoinfundibular pathways ([Kapur and Remington 1996](#); [Schmidt et al. 2001](#)). This effect suggests a mechanism for reduced liability for EPS compared with antipsychotics with unopposed  $D_2$  receptor antagonism and may contribute to therapeutic effects. Increased dopamine activity in the prefrontal cortex is linked to efficacy in improving the negative and cognitive symptoms of schizophrenia ([Stahl and Shayegan 2003](#)). Enhanced dopaminergic transmission in the tuberoinfundibular pathway minimizes the potential effect of  $D_2$  receptor antagonism on prolactin secretion. Ziprasidone's relatively high in vitro  $5-HT_{2A}/D_2$  receptor affinity ratio, compared with that of other second-generation antipsychotics (SGAs), predicts a low liability for

EPS and potential therapeutic benefits for negative symptoms ([Altar et al. 1986](#)).

## **Serotonin Type 1A, 1D, and 2C Receptor Activity**

Ziprasidone exhibits antagonist activity at serotonin type 1D (5-HT<sub>1D</sub>) and type 2C (5-HT<sub>2C</sub>) receptors and unusual (among SGAs) agonist activity at serotonin type 1A (5-HT<sub>1A</sub>) receptors ([DeLeon et al. 2004](#); [Schmidt et al. 2001](#)). The 5-HT<sub>1A</sub> affinity is comparable to that of buspirone, an agent with antidepressant and anxiolytic properties ([Mazei et al. 2002](#)), suggesting a mechanism that may contribute to beneficial effects on affective, cognitive, and negative symptoms in schizophrenia and schizoaffective disorder ([Díaz-Mataix et al. 2005](#); [Ichikawa et al. 2001](#); [Millan 2000](#); [Rollema et al. 2000](#); [Sumiyoshi et al. 2003](#); [Tauscher et al. 2002](#)). Potent antagonism at 5-HT<sub>1D</sub> receptors has been proposed to potentially mediate antidepressant and anxiolytic effects ([Briley and Moret 1993](#); [Zorn et al. 1998](#)). Blockade of 5-HT<sub>2C</sub> receptors disinhibits both dopamine and norepinephrine neurons in the cortex, an effect that could contribute to improvements in cognitive and affective abnormalities ([Bremner et al. 2003](#); [Bymaster et al. 2002](#); [Mazei et al. 2002](#); [Stahl 2003](#)).

Although 5-HT<sub>2C</sub> receptor antagonist activity might predict weight gain liability, based largely on a 5-HT<sub>2C</sub> knockout mouse model of obesity ([Tecott et al. 1995](#)), clinically significant predictive effects of 5-HT<sub>2C</sub> receptor antagonist activity on the relative weight gain risk associated with antipsychotic drugs have not been reliably detected ([Kroeze et al. 2003](#)), and the weight gain risk

associated with ziprasidone is among the lowest of currently available antipsychotics ([Allison et al. 1999b](#)).

## **Serotonin and Norepinephrine Transporter Activity**

Another important feature of ziprasidone is its relatively high affinity for serotonin and norepinephrine transporters ([Seeger et al. 1995](#); [Tatsumi et al. 1999](#)). In vitro, ziprasidone demonstrates dose-dependent reuptake inhibition of serotonin and norepinephrine transport, with effects ranging up to those of imipramine and amitriptyline ([Schmidt et al. 2001](#)), suggesting potential antidepressant activity. In vivo, the clinical significance of ziprasidone's monoaminergic reuptake inhibition may be limited by plasma protein binding or may be clinically relevant only at daily dosages higher than those currently approved. Monoaminergic reuptake inhibition is associated with hippocampal neurogenesis, suggesting potential value in countering the neuronal cell loss observed in both affective illness and schizophrenia ([Arango et al. 2001](#); [Duman 2004](#); [Thome et al. 1998](#)). Relevant to this activity, treatment with ziprasidone or risperidone is associated with an increase in cortical gray matter volume ([Garver et al. 2005](#)).

Ziprasidone has a low affinity for histaminergic type 1 ( $H_1$ ), muscarinic type 1 ( $M_1$ ), and  $\alpha_1$ -noradrenergic receptors. Among the biogenic amine receptors,  $H_1$  receptor antagonist activity is the largest predictor of weight gain liability ([Kroeze et al. 2003](#)).  $H_1$  antagonist activity also predicts sedative effects, which are potentially undesirable for patients aiming to maximize cognitive performance and social, occupational, and community engagement. Low affinity for  $\alpha_1$ -adrenergic receptors

predicts a lower likelihood of orthostatic hypotension and sedation with ziprasidone than with commonly used antipsychotics with potent  $\alpha_1$ -adrenergic receptor antagonist activity. Low affinity for  $M_1$  receptors predicts a low risk for anticholinergic side effects such as dry mouth, blurry vision, urinary retention, constipation, confusion, and memory impairment.

Ziprasidone's complex neuropharmacology provides explanatory support for observed treatment effects on psychotic and affective symptoms of schizophrenia, schizoaffective disorder, and bipolar disorder and for the observed favorable tolerability profile with minimal EPS and minimal metabolic side effects ([Stahl and Shayegan 2003](#)).

## Positron Emission Tomography Studies

An in vivo PET study ([Mamo et al. 2004](#)) examining the affinity of ziprasidone for  $D_2$  and  $5-HT_2$  receptors observed that optimal  $D_2$  receptor occupancy occurs at the high end of ziprasidone's initially recommended dosage range. In this study, the ziprasidone plasma concentration associated with 50% of maximal  $D_2$  receptor occupancy was more than twice the plasma concentration associated with 50% of maximal  $5-HT_2$  receptor occupancy. Using an imaging protocol where 60% or greater dopamine  $D_2$  receptor occupancy is generally predictive of antipsychotic activity, approximately 60%  $D_2$  occupancy was observed in relation to plasma concentrations equivalent to those attained with a dosage at or above 120 mg/day. These results, consistent

with clinical trial results discussed later in this chapter (see “Indications and Efficacy”), suggest that antipsychotic activity with ziprasidone is most commonly associated with dosages of 120 mg/day or greater ([Figure 30-2](#)).

**FIGURE 30-2.** Relationship between dopamine<sub>2</sub> ( $D_2$ ) and serotonin<sub>2</sub> ( $5-HT_2$ ) receptor occupancy and ziprasidone plasma levels in 16 patients with schizophrenia or schizoaffective disorder receiving therapeutic dosages of ziprasidone.

*Dotted straight lines* represent the minimum D<sub>2</sub> receptor occupancy and plasma concentration that would be expected to be associated with a clinical antipsychotic response, corresponding to a ziprasidone dosage of approximately 120 mg/day.

*Source.* Adapted from [Mamo et al. 2004](#).

## Dosing Recommendations

In addition to the PET data just described, evidence from clinical trials suggests that ziprasidone target dosages should be higher than those originally recommended. In the United States, it was initially recommended that ziprasidone treatment in patients with schizophrenia be initiated at a dosage of 20 mg twice daily, with the dosage then titrated at intervals of no less than 2 days to a maximum of 80 mg twice daily ([Pfizer Inc. 2008](#)). In contrast, subsequent FDA approval of ziprasidone for the treatment of bipolar mania included a recommendation that treatment be initiated at 40 mg twice daily with a more rapid titration; on the second day of treatment, the dosage might be increased to 60 or 80 mg twice daily, with subsequent adjustment based on tolerability and efficacy within a 40- to 80-mg twice-daily range.

Ziprasidone dosages of 120–160 mg/day are observed to be more effective than lower dosages in the treatment of acute schizophrenia ([Kane 2003b](#)) and bipolar disorders ([Citrome et al. 2009b](#)) in adults and also are associated with lower rates of medication discontinuation ([Citrome et al. 2009c](#)). A 6-month prospective, observational, naturalistic, uncontrolled study in Spain observed that dosages greater than 120 mg/day were associated with a lower risk of discontinuation for any cause ([Arango et al. 2007](#)). In an

analysis of commercial and Medicare prescription databases, [Citrome et al. \(2009a\)](#) observed significantly lower discontinuation rates among schizophrenia and bipolar disorder patients receiving ziprasidone at dosages of 120–160 mg/day compared with those receiving ziprasidone at lower dosages. Similarly, a European observational multicenter trial found that initial and overall underdosing of ziprasidone were associated with high discontinuation rates ([Kudla et al. 2007](#)), and a pooled analysis of both flexible-dose and fixed-dose studies ( $N=2,174$ ) observed greater efficacy in patients who received an initial dosage of 80 mg/day compared with patients who received an initial dosage of 40 mg/day ([Murray et al. 2004](#)). Finally, two large observational database analyses suggested that higher dosages of ziprasidone are associated with better treatment outcomes than lower dosages ([Joyce et al. 2006](#); [Mullins et al. 2006](#)). Both studies used prescription refills as an indicator of prescription adherence. [Joyce et al. \(2006\)](#) examined records from more than 1,000 commercially insured patients with schizophrenia or schizoaffective disorder and concluded that an initial daily dosage of 120–160 mg was associated with a significantly lower risk of medication discontinuation at 6 months than an initial daily dosage of 60–80 mg. [Mullins et al. \(2006\)](#) evaluated more than 1,000 Medicaid recipients with schizophrenia and similarly concluded that patients receiving an initial dosage of 120–160 mg/day had lower rates of medication discontinuation than patients receiving 20–60 mg/day. Reported clinical experience with ziprasidone has also suggested the need for dosages greater than 160 mg/day in selected patients ([Citrome et al. 2009a](#); [Harvey and Bowie 2005](#); [Nemeroff et al. 2005](#)). A dosage of 320 mg/day, twice the maximum

recommended dosage of 160 mg/day, did not lead to any additional symptom improvement in a small 8-week placebo-controlled trial as compared with a dosage of 160 mg/day, and plasma drug levels were similar between the two dosages at the end of the study period. There was a trend toward increasing diastolic blood pressure, more prominent negative symptoms, and greater QTc prolongation ([Goff et al. 2013](#)) with the 320 mg/day dosage.

Taken together, results from receptor occupancy studies, clinical trials, and pharmacoepidemiological analyses support the conclusion that initiation and treatment with ziprasidone at dosages greater than 120 mg/day, with rapid titration, are more likely to be effective than lower dosages in the treatment of schizophrenia, schizoaffective disorder, and bipolar disorder, while excessive dosages may incur additional side effects rather than additional efficacy.

---

## Pharmacokinetics and Disposition

---

### Absorption and Distribution

On the basis of evidence of enhanced absorption of ziprasidone in the presence of food, it is recommended that oral ziprasidone be taken with meals of at least 500 kcal to avoid substantial reduction in drug absorption ([Gandelman et al. 2009](#)) that cannot be effectively compensated for by increasing the dosage ([Citrome 2009](#)). Administration with food increases absorption by more than 50%, giving ziprasidone an oral bioavailability of approximately 60%

(Pfizer Inc. 2008). Maximal plasma concentration ( $C_{\max}$ ) is achieved within 3.7–4.7 hours and reaches 45–139  $\mu\text{g/L}$  in healthy volunteers receiving 20–60 mg twice daily, and steady-state serum concentrations occur within 1–3 days of twice-daily dosing (Hamelin et al. 1998; Miceli et al. 2000c). In contrast to oral administration, intramuscular administration of ziprasidone results in 100% bioavailability. A therapeutic plasma level is reached within 10 minutes, and  $C_{\max}$  is achieved within 30 minutes of administration of a 20-mg dose (Pfizer Inc. 2008).

The mean apparent volume of distribution of ziprasidone is 1.5 L/kg (Pfizer Inc. 2008), which is lower than that of many other antipsychotic drugs. Given the wider potential for unwanted interactions with various intracellular targets that has been observed with lipophilic drugs having a high volume of distribution (Dwyer et al. 1999), this may be a favorable attribute for ziprasidone and other similar compounds. Ziprasidone is more than 99% bound to plasma proteins.

## Metabolism and Elimination

Ziprasidone is extensively metabolized, with a mean terminal elimination half-life of approximately 7 hours after oral administration within the recommended clinical dosage range (Pfizer Inc. 2008). The elimination half-life of intramuscular ziprasidone is less than 3 hours with a single dose (Brook et al. 2000). Ziprasidone is cleared primarily via three metabolic pathways to yield four major circulating metabolites. Elimination occurs primarily through hepatic metabolism, with less than one-third of metabolic clearance mediated via cytochrome P450 (CYP)-catalyzed oxidation

and approximately two-thirds via reduction of the parent compound by aldehyde oxidase to dihydroziprasidone, which then undergoes *S*-methylation. The literature reports no commonly encountered clinically significant pharmacological inhibitors of aldehyde oxidase, suggesting limited real-world potential for drug-drug interactions that would alter the clinical activity of ziprasidone (Obach et al. 2004).

Additional secondary metabolic pathways include *N*-dealkylation (via CYP enzymes 3A4 and 1A2) and direct *S*-oxidation (via CYP3A4) (Beedham et al. 2003; Prakash et al. 2000). *S*-Methyl-dihydroziprasidone is the only active metabolite, with lower D<sub>2</sub> receptor affinity and no significant binding to H<sub>1</sub>, M<sub>1</sub>, or  $\alpha_1$ - and  $\alpha_2$ -adrenergic receptors. A small amount of the parent compound is excreted unchanged in the urine (<1%) and feces (<4%).

There are no clinically significant age- or sex-related differences in the pharmacokinetics of oral ziprasidone (Pfizer Inc. 2008). Hepatic impairment might be expected to increase the area under the time-concentration curve (AUC). A multiple-dose study (Everson et al. 2000) comparing subjects with clinically significant (Child-Pugh Class A and B) cirrhosis versus healthy control subjects indicated that 12 hours after administration of ziprasidone, the AUC was 13% and 34% greater in subjects with Child-Pugh Class A and B cirrhosis, respectively, than in matched control subjects, suggesting that dose adjustments are generally not mandatory for patients with hepatic impairment. Impairment in renal function is unlikely to significantly alter the pharmacokinetics of oral ziprasidone, suggesting that ziprasidone would not be removed by hemodialysis (Pfizer Inc. 2008). Intramuscular ziprasidone has not been systematically evaluated in the elderly or in

patients with hepatic or renal impairment. Intramuscular ziprasidone contains a cyclodextrin excipient that is cleared by renal filtration; thus, it should be administered with caution to patients with impaired renal function ([Pfizer Inc. 2008](#)).

## Impact of Food on Pharmacokinetics

Pharmacokinetic studies have examined ziprasidone bioavailability under fasting conditions and after eating food with varying caloric and fat composition to better understand effects of food intake on drug availability ([Gandelman et al. 2009](#); [Lombardo et al. 2007](#)). In an open-label, nonrandomized six-way crossover study, healthy adults received single doses of ziprasidone under fasting conditions and then under fed conditions with a standard meal of 800–1,000 calories. Dose-proportional increases in ziprasidone AUC and  $C_{\max}$  were observed under fed but not fasting conditions.  $C_{\max}$  was significantly higher in fed states than in fasting states at doses of 40 mg (63% higher) and 80 mg (97% higher). Results from two additional open-label crossover studies further clarified the factors regulating drug bioavailability ([Gandelman et al. 2009](#); [Lombardo et al. 2007](#)) and indicated that 1) medium-calorie meals (500 calories) are associated with ziprasidone exposure close to the exposure that can be achieved with high-calorie meals (1,000 calories) and nearly twice the exposure observed under fasting conditions, and 2) absorption is not significantly influenced by the fat content of the meal. These studies suggest that the administration of ziprasidone with even a low-fat meal of at least 500 calories provides linear pharmacokinetics and optimal

absorption. In addition, the results suggest that larger meal bulk, sufficient to slow gastric and duodenal transit time (e.g., a bowl of oatmeal), rather than fat content or specific calorie counts, may be an important contributor to reliable dose-dependent drug absorption with meals.

---

## Indications and Efficacy

---

### Schizophrenia and Schizoaffective Disorder

#### Acute Treatment

Ziprasidone is indicated for the acute treatment of schizophrenia and schizoaffective disorder. Its efficacy in the treatment of hospitalized patients with acute schizophrenia or schizoaffective disorder has been demonstrated in a series of double-blind, placebo-controlled trials of 4–6 weeks' duration ([Daniel et al. 1999](#); [Kane 2003b](#); [Keck et al. 1998, 2001](#)). Additional short-term (4- to 8-week) randomized, double-blind treatment studies using active antipsychotic comparator agents have indicated that ziprasidone has efficacy comparable to that of haloperidol, risperidone, and olanzapine for the treatment of positive symptoms and overall psychopathology ([Addington et al. 2004](#); [Goff et al. 1998](#); [Simpson et al. 2004a](#)). In a pooled analysis of four short-term placebo-controlled trials and three active-comparator trials, [Murray et al. \(2004\)](#) demonstrated that ziprasidone dosages of at least 120 mg/day, in comparison with lower dosages, are associated

with a more rapid and favorable response in overall psychopathology as well as a lower discontinuation rate due to inadequate clinical response, suggesting the importance of rapid titration to at least 120 mg/day ([Kane 2003b](#); [McCue et al. 2006](#)).

Suboptimal dosing, inadequate titration regimens, and failure to administer ziprasidone with food may have negatively affected its performance in some clinical trials. Some clinical trials included efficacy analyses on dosages that would now be considered suboptimal (i.e., <120 mg/day), whereas other studies used prolonged titration of ziprasidone, with a therapeutic dosage not reached until 1 week or more into the study. Clinical trials conducted before the release of pharmacokinetic data by [Lombardo et al. \(2007\)](#) may not have been designed to ensure that ziprasidone was administered with food for optimal oral absorption.

Ziprasidone has also been studied in the treatment of early psychosis and schizophrenia. In a study by [Johnsen et al. \(2010\)](#), patients admitted to the emergency ward with early psychosis were consecutively randomly assigned to receive one of several different SGAs: ziprasidone, olanzapine, quetiapine, or risperidone. No clinically significant differences in effectiveness of the tested antipsychotics emerged after a 2-year follow-up period. [Crespo-Facorro et al. \(2013, 2014\)](#), in a 12-week prospective open-label, randomized trial followed by a year-long extension period comparing quetiapine, aripiprazole, and ziprasidone for the treatment of first-episode psychosis, found significantly greater discontinuation rates with quetiapine than with aripiprazole or ziprasidone, owing to “insufficient” efficacy of quetiapine and comparable efficacy of the other two tested agents.

A series of meta-analyses found no consistent differences among the SGAs, either when comparing agents within the same class or when comparing SGAs with first-generation antipsychotics (FGAs) ([Bagnall et al. 2003](#); [Geddes et al. 2000](#); [Leucht et al. 1999](#); [Srisurapanont and Maneeton 1999](#); [Tandon and Fleischhacker 2005](#)). One meta-analysis of randomized controlled trials (RCTs) by [Davis et al. \(2003\)](#) suggested that although some SGAs (i.e., clozapine, risperidone, olanzapine, and amisulpride) were significantly more efficacious than FGAs, ziprasidone was not. It is important to note that this meta-analysis excluded data relating to low dosages of other antipsychotics (olanzapine <11 mg/day and risperidone <4 mg/day) but included data on ziprasidone dosages as low as 80 mg/day. In addition, the Davis et al. meta-analysis included relatively few studies of ziprasidone (4 studies as compared with 31 studies of clozapine, 22 studies of risperidone, and 14 studies of olanzapine), leaving significance testing for this agent more vulnerable to issues associated with individual studies. [Leucht et al. \(2013\)](#) used a novel approach, a Bayesian-framework, multiple-treatment meta-analysis of available RCT data, comparing 15 antipsychotic drugs and placebo in the acute treatment of schizophrenia, and concluded that antipsychotics differed substantially in side effects and that, while all antipsychotics were better than placebo, small but robust differences exist in efficacy, with clozapine representing the most effective—but not necessarily the best tolerated—antipsychotic.

Using Medicaid claims data, [Olfson et al. \(2012\)](#) compared the effectiveness (as measured by rates of medication discontinuation and hospital admission) of commonly prescribed SGA medications in child and adolescent outpatients (ages 6–17 years) with

schizophrenia or related disorders. Most youth with early psychosis (defined as onset before age 18 years) treated with quetiapine (70.7%), ziprasidone (73.3%), olanzapine (73.1%), risperidone (74.4%), or aripiprazole (76.5%) discontinued the medication within the first 180 days following medication initiation. Studies like these underscore both the comparable effectiveness among SGA agents and the high discontinuation rates associated with available treatments, the latter in part related to unwanted medication-induced adverse events. The favorable side-effect profile of ziprasidone recommends it as an important first-line option in the treatment of early psychosis.

---

## Maintenance Therapy

---

The maintenance efficacy of ziprasidone in treating schizophrenia and schizoaffective disorder has been studied in a series of double-blind and open-label extension trials ([Arato et al. 2002](#); [Hirsch et al. 2002](#); [Kane 2003a](#); [Schooler 2003](#); [Simpson et al. 2002, 2004b](#)). These studies indicate that long-term therapy with ziprasidone maintains clinical response and is effective in preventing relapse.

**Maintenance of effect.** In two maintenance-of-effect studies, patients with schizophrenia or schizoaffective disorder who had previously demonstrated acute response to treatment (defined as a  $\geq 20\%$  decrease in Positive and Negative Syndrome Scale [PANSS]-Total score and a Clinical Global Impression [CGI] scale score of  $\leq 2$ ) were randomly assigned to receive either ziprasidone or a comparator antipsychotic agent for at least 26 weeks ([Addington et al. 2009](#); [Schooler 2003](#); [Simpson et al. 2002](#),

2005). In both of these studies, the ziprasidone treatment groups demonstrated significant improvements from baseline in overall psychopathology, as measured by mean changes in symptom ratings using PANSS-Total, PANSS-Negative subscale, Brief Psychiatric Rating Scale-Depression Factor (BPRSd), and CGI-Severity (CGI-S) scores. These improvements were comparable to those seen in the olanzapine (Simpson et al. 2005) and risperidone (Addington et al. 2009) treatment groups.

**Relapse prevention.** To evaluate the efficacy of ziprasidone for relapse prevention, the Ziprasidone Extended Use in Schizophrenia (ZEUS) study enrolled stable inpatients with chronic schizophrenia and randomly assigned participants to 1 year of treatment with ziprasidone 40 mg/day ( $n=72$ ), 80 mg/day ( $n=68$ ), or 160 mg/day ( $n=67$ ) or placebo ( $n=71$ ), with a planned primary Kaplan-Meier analysis of time to relapse (Arato et al. 2002). In this study, all three dosages of ziprasidone were superior to placebo in the prevention of relapse. In addition, a penultimate-observation-carried-forward analysis (in which the last visit prior to relapse is excluded) was performed to filter out clinical worsening associated with relapse that might otherwise obscure symptom response trends during the rest of maintenance therapy (O'Connor and Schooler 2003). This analysis indicated that nonrelapsing patients treated with ziprasidone experienced modest symptomatic improvement during maintenance treatment. This study, like a number of other studies of other antipsychotic agents in schizophrenia patients, was limited by the relatively high level of attrition observed in all groups over the year of treatment.

## **Long-term response to treatment in symptomatic patients.**

A number of long-term double-blind trials designed to examine the efficacy of ziprasidone in symptomatic patients with schizophrenia have been performed ([Breier et al. 2005](#); [Hirsch et al. 2002](#); [Kinon et al. 2006](#); [Simpson et al. 2004a, 2005](#)). [Hirsch et al. \(2002\)](#) compared the efficacy of ziprasidone ( $n=148$ ) and haloperidol ( $n=153$ ) in a 28-week double-blind trial of stable outpatients with schizophrenia with prominent negative symptoms. In this study, ziprasidone and haloperidol were similarly efficacious in reducing overall psychopathology, with an advantage for ziprasidone in the percentage of patients classified as negative symptom responders. [Breier et al. \(2005\)](#) conducted a 28-week study of ziprasidone and olanzapine in outpatients as well as inpatients ( $N=548$ ) with active symptoms. In this study, olanzapine treatment was associated with greater improvement from baseline in total psychopathology scores (PANSS-Total, the primary efficacy measure) compared with ziprasidone and a higher rate of criterion-level response to treatment. [Simpson et al. \(2004a\)](#) conducted a 6-week double-blind, parallel-design flexible-dose comparison ( $N=269$ ) of ziprasidone ( $n=136$ ) and olanzapine ( $n=133$ ) in which patients who showed at least minimal response (CGI-Improvement [CGI-I] score  $\leq 2$  or  $\geq 20\%$  reduction in PANSS-Total score) were enrolled in a 6-month double-blind continuation trial ([Simpson et al. 2005](#)). In both the 6-week and the 6-month analyses, no differences between the treatment groups were detected on any primary (e.g., Brief Psychiatric Rating Scale [BPRS] total score, CGI-S) or secondary (e.g., PANSS-Total, CGI-I) measures.

[Potkin et al. \(2009\)](#) compared the effects of ziprasidone and haloperidol in a 196-week double-blind study using the Andreasen criteria for remission ([Andreasen et al. 2005](#)) by longitudinal analysis. During the initial 40-week study, no differences in PANSS or Global Assessment of Functioning Scale (GAF) score changes between the two antipsychotics compared emerged. In a subsequent 3-year extension study, ziprasidone-treated subjects were more likely to achieve remission (51%) compared with haloperidol-treated subjects (40%). The PANSS-Total and GAF score trajectories favored the higher 80–160 mg/day ziprasidone dosage as opposed to lower dosages, and the superior outcome for ziprasidone versus haloperidol may have been due in part to tolerability and adherence advantages.

**Clinical effectiveness.** There have been a number of effectiveness trials involving ziprasidone and using various definitions for *effectiveness*. The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) studies, funded by the National Institute of Mental Health (NIMH), included a long-term, double-blind, randomized study of patients with schizophrenia ( $N=1,493$ ; [Lieberman et al. 2005](#)). Phase 1 of the CATIE schizophrenia study compared ziprasidone, olanzapine, quetiapine, risperidone, and perphenazine on a primary endpoint of time to discontinuation for lack of efficacy or for any cause. Because of the timing of its FDA approval, ziprasidone was added to the study after enrollment had begun for all other treatment arms; this resulted in a smaller sample size for the ziprasidone treatment arm and some limitations regarding conclusions about ziprasidone in phase 1 of the study.

The primary analysis for the phase 1 study detected significant differences in time to discontinuation across the treatment groups overall. The longest time to discontinuation was in the olanzapine group. In the total study sample, no significant differences were seen in the time to discontinuation between the ziprasidone and olanzapine treatment groups, or between the ziprasidone group and other antipsychotic treatment groups.

Several considerations in this complex study are worth mentioning. Very few patients who entered the CATIE schizophrenia study were currently (i.e., prior to study entry) taking the relatively newly available medication, ziprasidone, compared with the number of patients taking the other antipsychotic medications in the trial. This resulted in a larger proportion of patients assigned to the ziprasidone treatment arm who were just starting to take a new medication and discontinuing their prior treatment. For example, 23% of subjects randomly assigned to receive olanzapine treatment were already receiving olanzapine monotherapy as their ongoing treatment, requiring no medication discontinuation or new drug initiation. Supplemental analysis of phase 1 CATIE data by [Essock et al. \(2006\)](#) indicated the overall importance, in terms of subsequent discontinuation rates, of whether randomized subjects were switching medications or whether the study randomization allowed them to continue receiving their prior treatment. A significantly higher rate of subsequent discontinuation was observed in patients who actually made a medication switch compared with those who were randomly assigned to stay with the same medication they had been taking prior to the trial. This effect of switching medications therefore favored treatment arms with a larger percentage of “nonswitchers” (i.e., olanzapine and

risperidone recipients in the CATIE phase 1 study). In a reanalysis of phase 1 CATIE data that excluded those patients randomly assigned to continue taking the antipsychotic that they were already taking at baseline, [Essock et al. \(2006\)](#) found that differences between rates of discontinuation in the ziprasidone group and rates in the other antipsychotic groups were attenuated, and no statistically significant differences in the primary outcome measure were observed for any agent.

The Ziprasidone Experience in Schizophrenia in Germany/Austria (ZEISIG) study investigated the effectiveness of ziprasidone as measured by discontinuation rates and mean changes on the BPRS Total score in moderately ill and reasonably stable patients ( $N=276$ ) with schizophrenia or schizoaffective disorder ([Kudla et al. 2007](#)). Approximately 60% of subjects discontinued ziprasidone prematurely, most within the first 4 weeks of study treatment. Among study completers, ziprasidone was associated with significant improvements in BPRS total score. The relatively high rate of discontinuation may be explained in part by the planned dosing strategy. In this study, ziprasidone use was initiated at a low dosage of 40 mg/day, which is now known to be associated with higher discontinuation rates and shorter durations of therapy compared with higher dosages ([Joyce et al. 2006](#); [Mullins et al. 2006](#)). The maximal dosage allowed was 160 mg/day, which may be insufficient for some patients ([Harvey and Bowie 2005](#); [Nemeroff et al. 2005](#)).

[Arango et al. \(2007\)](#), of the Ziprasidone in Spain Study Group, examined the effectiveness of ziprasidone ( $N=1,022$  in the primary analysis sample) as measured by response rate (defined as a  $\geq 30\%$  reduction in the PANSS-Total score). Nearly half of the patients experienced the defined

level of clinical response, and patients overall had significant and clinically relevant mean reductions in both the PANSS-Total score and the Positive, Negative, and General Psychopathology subscale scores (effect sizes were 1.60, 1.83, 0.62, and 1.40, respectively). Compared with lower dosages, ziprasidone dosages greater than 120 mg/day were associated with a lower risk of discontinuation for any cause.

[Díaz-Marsá et al. \(2009\)](#) conducted a prospective, uncontrolled, naturalistic study to evaluate the effectiveness and tolerability of oral ziprasidone in psychiatric inpatients with an acute exacerbation of schizophrenia or schizoaffective disorder. Among the 196 patients enrolled, the mean dosage of ziprasidone at discharge was  $186.3 \pm 67.7$  mg/day. Progressive and statistically significant improvements in BPRS- and CGI-measured symptom severity were observed from the first week through discharge (after  $23.4 \pm 34.2$  days). Changes from baseline to study endpoint were deemed clinically relevant, with reported effect sizes greater than  $d=0.8$ , indicating that the results are of notable clinical—not just statistical—significance.

The European First Episode Schizophrenia Trial (EUFEST; [Kahn et al. 2008](#)) included 49 sites in Europe and Israel and assessed 498 first-episode patients ages 18–40 years who had experienced psychosis for less than 2 years, had been exposed to antipsychotic drugs for less than 2 weeks during the preceding year, and had less than 6 weeks of total lifetime exposure to antipsychotic drugs. Participants were randomly assigned to receive haloperidol (which served as the FGA comparator) 1–4 mg/day, amisulpride 200–800 mg/day, olanzapine 5–20 mg/day, quetiapine 200–750 mg/day, or ziprasidone 40–160 mg/day

and were followed up for 1 year. Analysis of all-cause treatment discontinuation revealed rates of 40% for haloperidol, 40% for amisulpride, 33% for olanzapine, 53% for quetiapine, and 45% for ziprasidone. Symptom reductions were similar in all groups (approximately 60%). In addition to efficacy considerations, tolerability differences—whether due to different pharmacological profiles or to patient preferences—should guide the clinician in choosing an appropriate first-line treatment.

## **Efficacy by Symptom Type**

**Efficacy for cognitive symptoms of schizophrenia.** The effect of ziprasidone on cognitive function in schizophrenia patients was evaluated by a battery of cognitive tests included in a double-blind olanzapine comparator study that evaluated changes at 6 weeks and 6 months ([Harvey et al. 2004, 2006a](#)). Antipsychotic treatment with ziprasidone and with olanzapine both resulted in significant cognitive improvements from baseline in attention memory, working memory, motor speed, and executive functions, with olanzapine also associated with improvement in verbal fluency. Further improvements in both treatment groups were observed from the end of 6 weeks to the 6-month assessment time point on verbal learning, executive functioning, and verbal fluency, with no differences between treatment groups. It should be noted that despite these improvements, a substantial proportion of patients studied continued to experience clinically significant cognitive impairment posttreatment. Neuropsychological improvements in general are not related to clinical changes ([Harvey et al. 2006b](#)).

Data from the CATIE schizophrenia study indicate that treatment with all of the antipsychotics tested (i.e., ziprasidone, perphenazine, olanzapine, risperidone, and quetiapine) was associated with a small but significant improvement in cognition after 2 months of treatment, with no significant difference between ziprasidone and the other antipsychotics ([Keefe et al. 2007](#)). Cognitive improvement predicted a longer time to treatment discontinuation, independent of symptom improvement, in patients treated with quetiapine or ziprasidone.

**Efficacy for affective symptoms.** Ziprasidone has been hypothesized to be a promising treatment for mood disorders, based on its unique in vitro potency as a serotonin and norepinephrine reuptake inhibitor comparable to that of known antidepressants (see “Neuropharmacology and Receptor-Binding Profile” section earlier in this chapter). Addressing the question of ziprasidone’s potential antidepressant efficacy in schizophrenia patients with comorbid affective symptoms, data can be examined from randomized, double-blind, placebo-controlled clinical trials ([Daniel et al. 1999](#); [Keck et al. 1998, 2001](#)) and from double-blind head-to-head trials comparing ziprasidone with risperidone or olanzapine ([Kane 2003b](#)). The results of placebo-controlled studies ([Daniel et al. 1999](#); [Keck et al. 1998](#)) suggest that treatment of schizophrenia and schizoaffective disorder with ziprasidone is associated with significant improvement in comorbid depressive symptoms, based on intent-to-treat analyses, but sometimes only in the subset of patients with higher levels of baseline depression. The baseline severity of depressive symptoms in these studies tends to be relatively mild, so subgroups of patients with more

pronounced comorbid depressive symptoms at baseline were also analyzed; the antidepressant effect of ziprasidone was larger than that of placebo in these analyses. In the two active-comparator studies, improvement in depression and anxiety symptoms in patients receiving ziprasidone was comparable to the improvement in olanzapine recipients but greater than the improvement in risperidone recipients. A smaller study ([Kinon et al. 2006](#)) compared the efficacy of olanzapine and ziprasidone over 24 weeks in the treatment of schizophrenia or schizoaffective disorder patients with prominent depressive symptoms. Both treatment groups had significant improvements in depressive symptoms for the first 8 weeks, with olanzapine-treated patients showing significantly greater improvements in depressive symptoms at study endpoint. However, interpretation of the findings from this study is limited by that fact that a substantial number of patients (52.8% of  $N=394$  at study entry) received concurrent treatment with nonstandardized antidepressants. These overall results provide preliminary evidence suggesting that ziprasidone, like some other antipsychotic agents, may be effective in treating comorbid depressive symptoms in patients with schizophrenia and schizoaffective disorder.

**Efficacy for social deficits and improvement in quality of life.** The NIMH CATIE study is the largest trial to date to have examined the effect of ziprasidone and other antipsychotics on psychosocial functioning in patients with schizophrenia ([Swartz et al. 2007](#)). This study employed the Quality of Life Scale, a widely used clinician-rated measurement ([Heinrichs et al. 1984](#)), to assess changes in social functioning, interpersonal relationships, vocational functioning, and psychological well-being. One-

third of the patients in the phase 1 study antipsychotic treatment groups made modest improvements on the Quality of Life Scale from baseline to the 12-month endpoint (average effect size, 0.19 standard deviation units), with no significant differences between the agents.

The effect of ziprasidone on social functioning has also been evaluated using the Prosocial subscale of the PANSS, including items related to active and passive social avoidance, emotional withdrawal, stereotypical thinking, and suspiciousness ([Purnine et al. 2000](#)). In three separate but related studies from one group, stable patients taking FGAs, olanzapine, or risperidone were switched to ziprasidone and followed for 6 weeks with ratings of safety, efficacy, and effectiveness ([Weiden et al. 2003b](#)). Six weeks of treatment with ziprasidone in all three prior-treatment groups resulted in significant improvement on the PANSS Prosocial subscale ([Loebel et al. 2004](#)). The interpretation of results as being specific to ziprasidone use, rather than being simply an effect of extended, closely monitored treatment, is complicated by the absence of a control other than pretreatment baseline ratings.

[Harvey et al. \(2009\)](#) examined quality-of-life changes in community-dwelling patients with schizophrenia randomly assigned to receive either haloperidol ( $n=47$ ) or ziprasidone ( $n=139$ ) over a follow-up interval of up to 196 weeks. Long-term treatment with ziprasidone was associated with greater functional gains than treatment with haloperidol. Both treatment retention and functional gains favored ziprasidone in this long-term study, suggesting superior efficacy and tolerability, which may reflect back favorably on adherence rates. Post hoc analysis revealed the most significant quality-of-life improvements in the high-dosage ziprasidone group (80–160 mg/day) ([Stahl](#)

[et al. 2010b](#)), concordant with recent recommendations that higher dosages of ziprasidone may be more effective than lower dosages.

## **Treatment-Resistant Schizophrenia**

Several studies have evaluated ziprasidone use in refractory schizophrenia, albeit using different criteria for “refractory.” A 12-week double-blind comparison of ziprasidone and chlorpromazine ( $N=306$  patients) defined treatment-resistant status as inability to achieve criterion-level response after 6 weeks of prospective treatment with haloperidol ([Kane et al. 2006](#)). The mean daily dose of ziprasidone at study endpoint was approximately 154 mg, compared with a mean daily chlorpromazine dose of approximately 744 mg. Treatment with ziprasidone produced significantly greater improvement at endpoint in PANSS–Negative subscale scores compared with chlorpromazine. In addition, ziprasidone treatment was associated with a 1.3-fold higher likelihood of achieving a 50% reduction in BPRS total score compared with chlorpromazine treatment. The Monitoring Oral Ziprasidone As Rescue Therapy (MOZART) study in antipsychotic-resistant/intolerant patients ([Sacchetti et al. 2009](#)), an 18-week randomized, flexible-dose, double-blind trial, evaluated ziprasidone as an alternative to clozapine in treatment-refractory schizophrenia. Patients had a history of nonresponse and/or intolerance to at least three acute cycles of different antipsychotic medications given at therapeutic doses, with persistent PANSS–Total scores of at least 80. Patients were randomly assigned to receive ziprasidone 80–160 mg/day or clozapine 250–600 mg/day. A progressive and significant reduction from baseline in PANSS–Total score was observed from day 11 in both study

arms, without between-drug differences and with similar rates of early discontinuation due to adverse events. Ziprasidone had a more tolerable metabolic profile in the short-term treatment.

A small amount of literature suggests that the addition of a second antipsychotic medication to clozapine in patients who do not respond to or cannot tolerate standard dosages of clozapine may provide additional benefits. In the context of safety concerns and increasing health care costs, there is currently limited empirical evidence for the efficacy and safety of such antipsychotic combinations ([Kreyenbuhl et al. 2007](#)). However, adjunctive treatment with ziprasidone or risperidone, for example, was found helpful in patients with refractory schizophrenia that was incompletely responsive to clozapine ([Zink et al. 2009](#)). Both adjunctive antipsychotics produced additional reductions on PANSS-Positive and -Negative symptom subscale scores after 6 weeks of treatment, and the intervention was well tolerated. Further investigations are needed before definitive recommendations can be made, and treatment resistance should be operationalized uniformly so as to facilitate comparative research.

## **Switching From Other Antipsychotics**

The efficacy of ziprasidone has been found to be comparable to that of other SGAs and FGAs during both acute and maintenance treatment of schizophrenia and schizoaffective disorder. Evidence also points to the safety—particularly the cardiometabolic safety—of ziprasidone compared with other antipsychotics (see “Side Effects and Toxicology” section later in this chapter). These results support interest in switching from antipsychotic treatment with other agents to treatment with ziprasidone.

Several open-label medication-switching studies evaluated strategies for switching from other antipsychotics to ziprasidone on measures of efficacy, safety, and tolerability, including the effect of different titration schedules on the outcome ([Weiden et al. 2003b](#)). In each study, patients were randomly assigned to one of three switching strategies to be completed in 1 week: 1) immediately discontinuing the previous antipsychotic and immediately starting ziprasidone the next day; 2) lowering the dose of the previous antipsychotic by half while simultaneously starting ziprasidone; or 3) overlapping the start of ziprasidone with the full dosage of the prior antipsychotic and then gradually reducing the prior antipsychotic dosage after 4 days of ziprasidone therapy.

For these switching strategies, the starting dosage of ziprasidone was 80 mg/day (40 mg twice daily), with subsequent dosage adjustments based on clinical judgment. In one study, patients taking high-potency FGAs such as haloperidol ( $N=108$ ) were switched to ziprasidone. In the second study, patients ( $N=58$ ) were switched from risperidone to ziprasidone. In the third study, patients ( $N=104$ ) were switched from olanzapine to ziprasidone. Discontinuation rates were low in all three studies, ranging from 2%–6% for lack of efficacy to 6%–9% for adverse events. Among study completers, statistically significant improvements were observed in PANSS-Total, PANSS-Positive, and PANSS-Negative subscale scores and BPRS total scores. Different switching strategies were not associated with a different likelihood of trial completion or different magnitude of clinical response.

[Rossi et al. \(2011\)](#) examined pooled data from 10 previously completed “switch” studies involving a total of 1,395 patients who were switched to ziprasidone. Switching

from FGAs or other SGAs generally resulted in maintenance or improvement of efficacy across all studied symptom domains, including improvements in tolerability and acute and long-term benefits regarding cardiometabolic parameters. The recommended titration schedule was a “plateau cross-titration strategy,” which the authors described as rapid uptitration of ziprasidone to a dosage range of 60–80 mg administered twice daily with food. To facilitate the crossover and minimize patient discomfort, temporary coadministration of benzodiazepines, anticholinergics, or beta-blockers was recommended for management of potential rebound effects due to differences in pharmacological profiles of the pre-switch medications and ziprasidone.

The balance of the evidence from studies examining strategies for switching to ziprasidone favors rapid uptitration of ziprasidone to a comparatively higher dosage (up to 160 mg/day) combined with rapid discontinuation of the previous agent, including management of specific rebound effects combined with close clinical monitoring during the switch. Predictable changes in tolerability (e.g., weight loss when switched from olanzapine, reduction in EPS when switched from haloperidol) are observed along with maintenance of efficacy.

## Bipolar Disorder

### **Acute Mania**

Ziprasidone has received regulatory approval (e.g., by the FDA) for the acute treatment of bipolar mania, with efficacy for acute mania demonstrated in two double-blind, placebo-controlled trials, each 3 weeks in duration, in patients with

bipolar I disorder (Keck et al. 2003b; Potkin et al. 2005). In both studies, onset of action was rapid (within 48 hours) and sustained through 3 weeks of treatment in patients with bipolar mania or bipolar mixed states, with or without psychotic symptoms. (The results of the study by Keck et al. [2003b] are shown in Figure 30-3.) At endpoint, approximately half of the treated patients from both studies met response criteria for mania ( $\geq 50\%$  reduction in Mania Rating Scale [MRS] scores).

**FIGURE 30-3.** Effect of ziprasidone on mania: rating scale scores in patients with bipolar disorder receiving 21-day randomized treatment with ziprasidone or placebo.

\* $P < 0.003$  (F test), placebo-treated patients versus ziprasidone-treated patients.

\*\* $P < 0.001$  (F test), placebo-treated patients and ziprasidone-treated patients.

*Source.* Adapted from [Keck et al. 2003b](#).

A number of placebo-controlled trials evaluating the efficacy of short-term monotherapy with various antipsychotics, including haloperidol, ziprasidone, olanzapine, risperidone, quetiapine, and aripiprazole, have demonstrated comparable improvement in symptoms of mania ([Bowden et al. 2005](#); [Hirschfeld et al. 2004](#); [Keck et al. 2003a, 2003b](#); [Khanna et al. 2005](#); [McIntyre et al. 2005](#); [McQuade et al. 2003](#); [Potkin et al. 2005](#); [Sachs et al. 2006](#); [Smulevich et al. 2005](#); [Tohen et al. 1999, 2000](#); [Vieta et al. 2010](#); [Weisler et al. 2003](#)). Two large meta-analyses of randomized, placebo-controlled trials have examined the relative efficacy of various SGAs for the adjunctive treatment of mania ([Perlis et al. 2006](#); [Scherk et al. 2007](#)). Although the statistical results of the two meta-analyses are similar, the authors of each study interpreted the results somewhat differently. [Perlis et al. \(2006\)](#) concluded that add-on therapy with SGAs (ziprasidone, olanzapine, quetiapine, and risperidone) conferred an additional benefit over monotherapy with a traditional mood stabilizer in reducing manic symptoms, with no difference in efficacy among the drugs. [Scherk et al. \(2007\)](#) also concluded that SGAs as a group were significantly superior to placebo as adjunctive treatment for mania but that ziprasidone and other individual agents may not be significantly superior to placebo in the adjunctive treatment of manic symptoms. This conclusion is in contrast with results reported by [Vieta et al. \(2010\)](#) from a 12-week double-blind two-part study in 438 adults with bipolar-associated acute mania. In the first part, a 3-week period in which ziprasidone (80–160 mg/day) and placebo were compared with haloperidol (8–30 mg/day) as a reference standard, changes from baseline

MRS scores for ziprasidone and haloperidol were superior to those for placebo beginning with day 2 of treatment until week 3. At week 3, response rates were 36.9%, 54.7%, and 20.5%, respectively, for ziprasidone, haloperidol, and placebo. In the 9-week extension phase to examine tolerability, during which ziprasidone replaced placebo, improvements were maintained for 96.3% of patients receiving haloperidol and 88.1% of those receiving ziprasidone, with ziprasidone demonstrating superior tolerability.

Finally, regulatory approvals for the individual agents have supported the efficacy and safety of a number of individual antipsychotics for the acute treatment of mania, including ziprasidone (which is also approved for the acute treatment of mixed states). Prospective head-to-head comparator trials like that of [Vieta et al. \(2010\)](#) may further clarify whether differences in efficacy suggested by some meta-analyses are clinically informative or merely related to limitations in study design or methodology (e.g., underdosing of ziprasidone or dosing without food).

## **Bipolar Depression**

Preliminary results indicate that ziprasidone may be a viable treatment option in bipolar depression. For example, an 8-week open-label study investigating ziprasidone monotherapy for depressive symptoms in bipolar II patients ( $n=30$  completers) demonstrated effective attenuation of depression with a relatively low mean dosage of 58 mg/day ([Liebowitz et al. 2009](#)). The authors concluded that larger and controlled trials are required to confirm their findings.

## **Dysphoric Mania**

Dysphoric mania is a common and often difficult-to-treat subset of bipolar mania that is associated with significant depressive symptoms. Data from a post hoc analysis of two similarly designed 3-week placebo-controlled trials ([Stahl et al. 2010a](#)) in acute bipolar mania that were pooled and analyzed indicated that ziprasidone significantly improved both depressive and manic mood symptoms in patients with dysphoric mania. A meta-analysis by [Muralidharan et al. \(2013\)](#) suggested that SGAs, including ziprasidone, are effective for the treatment of mixed states of bipolar disorder with predominant manic symptoms. A number of trials could not be included because data for mixed episodes were not presented separately. Similar to the preliminary results obtained in bipolar depression, definitive conclusions await further prospective controlled trials.

## **Maintenance Treatment**

Two 52-week open-label extension studies support the safety, tolerability, and sustained efficacy of ziprasidone as maintenance treatment for bipolar disorder (P.E. [Keck et al. 2004, 2009](#); [Weisler et al. 2004](#)). P.E. [Keck et al. \(2004\)](#) reported that treatment with ziprasidone ( $n=127$ ; mean dosage, 123 mg/day) was associated with significantly lower MRS and CGI-S scores compared with baseline, beginning as early as the first week. Overall, improvements in manic symptoms achieved during acute treatment continued to consolidate during maintenance treatment with ziprasidone. During 52 weeks of treatment, only 6% of patients discontinued ziprasidone use because of relapse of mania. Similarly, only 4% of patients discontinued because of a clinical switch into depression. An important caveat regarding these results is the high rate of attrition

observed by the end of 1 year, which is consistent with long-term studies involving other SGAs but still limits the full interpretation of results. Comparable results were observed in a separate extension study of adjunctive ziprasidone therapy (mean dosage, 92.6 mg/day) by [Weisler et al. \(2004\)](#); this study reported a mean improvement from baseline in MRS scores at all points throughout the study ([Patel and Keck 2006](#)). Finally, subjects with DSM-IV bipolar I disorder achieving 8 or more consecutive weeks of stability with open-label ziprasidone (80–160 mg/day) and lithium or valproate were randomly assigned in a 6-month double-blind maintenance period to receive ziprasidone plus mood stabilizer or placebo plus mood stabilizer. The time to intervention for a mood episode and the time to discontinuation for any reason were significantly longer for ziprasidone compared with placebo ([Bowden et al. 2010](#)), indicating that ziprasidone may be useful in combination with a classic mood stabilizer for maintenance of euthymia in bipolar disorder.

## Treatment-Resistant Depression

A randomized, double-blind, placebo-controlled study, as well as a series of uncontrolled studies, has sparked interest in the efficacy of ziprasidone for depression, especially treatment-resistant depression ([Barbee et al. 2004](#); [Jarema 2007](#); [Papakostas et al. 2004, 2015](#)).

[Papakostas et al. \(2004\)](#) reported the results of a small study of 20 patients with major depression resistant to treatment with selective serotonin reuptake inhibitors (SSRIs). Open-label treatment with ziprasidone for 6 weeks, adjunctive to ongoing SSRI treatment, was evaluated with

an intent-to-treat analysis that identified 10 treatment responders (defined as having a  $\geq 50\%$  decrease in depressive symptoms as measured by the 17-item version of the Hamilton Rating Scale for Depression (Ham-D-17). In order to further evaluate these effects, a randomized, double-blind, placebo-controlled trial was conducted to compare adjunctive ziprasidone with adjunctive placebo among 139 adult outpatients with major depressive disorder (MDD) that had not responded to an 8-week open-label trial of escitalopram alone ([Papakostas et al. 2015](#)). Compared with the patients randomly assigned to receive adjunctive placebo, those assigned to receive adjunctive ziprasidone (mean dosage, 98 mg/day; SD=40) with escitalopram demonstrated significantly greater rates of clinical response as well as significantly greater improvement on the Ham-D-17 Total score and the Hamilton Rating Scale for Anxiety score. Ziprasidone has also been tested in non-treatment-resistant depression. A 12-week randomized, double-blind, placebo-controlled sequential parallel comparison trial of ziprasidone as monotherapy for MDD in 120 outpatients with depression conducted by [Papakostas et al. \(2012\)](#) showed no significant efficacy for ziprasidone compared with placebo. The authors suggested that a larger trial may be required to detect significant differences.

## Agitation

The efficacy of intramuscular ziprasidone for the treatment of agitated psychosis has been demonstrated in two randomized double-blind trials (2 mg intramuscular vs. 10 mg or 20 mg intramuscular, respectively, with up to three

more doses allowed as needed at 4-hour or 2-hour intervals, respectively), leading to regulatory approval by the FDA ([Daniel et al. 2001](#); [Lesem et al. 2001](#)). Treatment with single 10- or 20-mg doses leads to rapid reductions in symptom severity, with most patients having remission of agitation within 1 hour of dosing. Treatment with intramuscular ziprasidone is associated with a relatively low rate of concomitant benzodiazepine use (<20%) and may be better tolerated than haloperidol ([Zhang et al. 2013](#)). Sequential use of intramuscular ziprasidone followed by oral ziprasidone for the treatment of acute psychotic agitation has demonstrated superior efficacy, compared with sequential use of intramuscular and oral haloperidol, in two 7-day randomized open-label trials ([Brook et al. 2000](#); [Swift et al. 1998](#)) as well as in a 6-week randomized, single-blind, flexible-dose study ([Brook et al. 2005](#)). Clinical improvement occurred more rapidly than with haloperidol in one study and as quickly as 30 minutes after the first intramuscular administration of ziprasidone ([Swift et al. 1998](#)). Cumulative data from these studies indicate that intramuscular ziprasidone can rapidly control agitation and psychotic symptoms and provide greater mean improvements in acute agitation than seen with intramuscular haloperidol (e.g., greater mean improvements in BPRS total score, agitation, and CGI-S score) ([Brook 2003](#)).

## Pediatric Use

Ziprasidone is not approved in the United States by the FDA for use in pediatric patients. Its use has been evaluated in children and adolescents (ages 10–17 years)

experiencing manic or mixed episodes associated with bipolar disorder ([Kuehn 2009](#)). In the European Union it has been approved for the treatment of bipolar disorder (mania) in pediatric patients. Results from RCTs of ziprasidone in children and adolescents (ages 10–17 years) with bipolar disorder ([Versavel et al. 2005](#)) and with bipolar disorder, schizophrenia, or schizoaffective disorder ([DelBello et al. 2008](#)) have been reported. In the former study, treatment with ziprasidone was associated with improvement in mania and overall psychopathology ([Versavel et al. 2005](#)). The latter study focused on safety and did not report any unexpected tolerability findings in this age population, using a starting dosage of 20 mg/day titrated to between 80 and 160 mg/day over 1–2 weeks for clinically determined optimal dosing ([DelBello et al. 2008](#)). Finally, a 4-week acute randomized, placebo-controlled multicenter trial, followed by a 26-week open-label extension study, in pediatric patients with bipolar disorder (ages 10–17 years) showed benefits of ziprasidone and a benign short-term side-effect profile ([Findling et al. 2013a](#)). In pediatric schizophrenia, in a study using a 6-week randomized (2:1), double-blind, placebo-controlled design, ziprasidone did not separate from placebo ([Findling et al. 2013b](#)).

---

## Side Effects and Toxicology

---

### Tolerability Profile in Clinical Trials

Ziprasidone has a favorable tolerability profile based on both short- and long-term clinical trials ([Daniel 2003](#); [Pfizer](#)

[Inc. 2004](#)). The four most common treatment-related adverse events associated with oral ziprasidone in short-term premarketing placebo-controlled trials for schizophrenia were somnolence (14%), EPS (14%), nausea (10%), and constipation (9%) ([Pfizer Inc. 2008](#)). In subsequent clinical trials, treatment with ziprasidone was associated with a low occurrence of adverse events, most of which were considered mild to moderate in severity ([Arango et al. 2007](#); [Arato et al. 2002](#); [Lieberman 2007](#); [Nemeroff et al. 2005](#); [Weiden et al. 2002, 2003b](#)). In addition to the comprehensive listing of potential adverse events available in the full U.S. prescribing information (USPI) ([Pfizer Inc. 2008](#)), published case reports offer accounts of various rare adverse events that may be associated with the use of ziprasidone ([Akkaya et al. 2006](#); [Kaufman et al. 2006](#); [Miodownik et al. 2005](#); [Murty et al. 2002](#); [Villanueva et al. 2006](#)).

Intramuscular ziprasidone shows a favorable tolerability profile similar to that of oral ziprasidone. In premarketing trials of intramuscular ziprasidone, the most common side effects (those with an incidence of >5% and an incidence greater than that seen in placebo recipients) were somnolence (20%), headache (13%), and nausea (12%) ([Pfizer Inc. 2008](#)). Pooled data from clinical trials of intramuscular ziprasidone indicate that most treatment-related adverse events were mild to moderate in severity, with the most common side effects being headache, nausea, dizziness, insomnia, anxiety, and pain at the injection site ([Daniel 2003](#); [Zimbroff et al. 2002](#)).

## Safety in Pregnancy

Ziprasidone is considered a Category C drug in pregnancy. Although some specific developmental effects have been noted in animal studies at dosages ranging from 0.5 to 8.0 times the maximal recommended human dosage ([Pfizer Inc. 2008](#)), there are as yet no similar reports of such effects in humans. The reader is advised to consult the current USPI for a detailed listing of potential adverse drug effects identified in the regulatory approval process and postmarketing surveillance.

## Increased Mortality Risk in Elderly Patients With Dementia-Related Psychosis

In 2005, the FDA mandated the addition of a black box warning in the USPI regarding an increased risk of mortality associated with the use of both SGAs and FGAs in elderly patients with dementia-related psychosis. Observed causes of death have been varied, and the mechanism of any drug effect in schizophrenia remains uncertain ([Pfizer Inc. 2008](#)). In particular, it remains unclear to what extent these uncontrolled observations of increased mortality are due to specific drug effects or to the advanced medical risk characteristics of patients with dementia or delirium who tend to receive these medications ([Farber et al. 2000](#); [Rochon et al. 2008](#)). A recent retrospective cohort study among antipsychotic-exposed older adults did not find increased mortality associated with ziprasidone, in contrast with haloperidol, olanzapine, and risperidone ([Gerhard et al. 2014](#)).

Retrospective analysis of intramuscular use of ziprasidone, olanzapine, or haloperidol in large matched cohorts of hospitalized patients did not indicate significant differences in mortality rates among the three cohorts ([Holdridge et al. 2010](#)).

## Activation Effects

Clinical experience with ziprasidone in the years following initial U.S. approval has suggested that a small subgroup of patients may experience insomnia, or what has been characterized as *activation* or *akathisia*, soon after initiation of treatment ([Nemeroff et al. 2005](#)). These presentations have been described as transient manifestations of anxiety, restlessness, insomnia, increased energy, or hypomania-like symptoms, occurring most commonly at what is now considered the lower end of the dosage range. Anecdotal reports suggest that starting dosages of 120 mg/day or greater and more rapid dose titration can substantially reduce the incidence of these clinical presentations ([Weiden et al. 2002](#)). These anecdotal clinical observations are consistent with controlled experimental evidence indicating that a significantly lower rate of discontinuation occurs in patients who begin ziprasidone therapy at higher dosages (120–160 mg/day) than in patients who receive initial dosages of 80 mg/day or less ([Joyce et al. 2006](#)). Several mechanisms may explain these observations. First, ziprasidone is less intrinsically sedating than many other antipsychotics in current use (e.g., due to less H<sub>1</sub> receptor antagonism), so that patients initiating ziprasidone treatment after months or years of receiving a more sedating therapy may experience initial

difficulties adjusting to the new level of drug-related sedation. Second, as discussed earlier in this chapter (see “Pharmacological Profile” and “Indications and Efficacy” sections), many patients have been treated with ziprasidone at dosages that were insufficient to achieve optimal D<sub>2</sub> receptor blocking, leading to undertreatment of the underlying illness compared with what might have been achieved with an appropriately dosed prior therapy.

Furthermore, ziprasidone underdosing with respect to D<sub>2</sub> receptor binding can produce a well-understood but unwanted pharmacodynamic situation with respect to the differential balance of 5-HT<sub>2C</sub> receptor antagonism relative to D<sub>2</sub> receptor antagonism. As was illustrated in [Figure 30-2](#), use of ziprasidone dosages at the lower end of the clinical dosage range can allow 5-HT<sub>2</sub> receptors to reach 50% or greater maximal receptor occupancy well before clinically significant levels of D<sub>2</sub> receptor occupancy are achieved ([Mamo et al. 2004](#)). 5-HT<sub>2C</sub> receptor antagonist activity at this level disinhibits cortical monoaminergic neurotransmission (e.g., dopamine release), which, in the absence of sufficient D<sub>2</sub> receptor blockade, may lead to clinically relevant excess monoaminergic neurotransmission ([Bonaccorso et al. 2002](#); [Pozzi et al. 2002](#)). Clinicians commonly address these potential issues through appropriate dosing and through the transient targeted use of concomitant medication strategies (e.g., adjunctive benzodiazepine treatment) for relevant patients starting new treatment in the acute inpatient setting or for stable outpatients needing a smooth transition to new therapy.

## DRESS Syndrome

In 2014, the FDA issued a warning that ziprasidone is one of more than 50 medications associated with a rare condition called Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS) syndrome. This potentially life-threatening hypersensitivity reaction presents as a skin rash with fever, eosinophilia, lymphadenopathy, and multiorgan inflammation. Patients who develop this constellation of symptoms during treatment with ziprasidone should be evaluated for possible DRESS syndrome, and if that syndrome is suspected, their medication should be discontinued ([Cacoub et al. 2011](#)).

## Extrapyramidal, Metabolic, and Cardiac Adverse Effects

### Extrapyramidal Side Effects

Short-term trials indicate that treatment with ziprasidone is associated with a larger incidence of EPS compared with treatment with placebo ([Pfizer Inc. 2008](#); [Potkin et al. 2005](#)). In contrast, data from a 52-week trial ([Arato et al. 2002](#)) indicate that the incidence of abnormal movement disorders during treatment with ziprasidone is comparable to the incidence during placebo treatment. Other long-term studies suggest a low (<6%) incidence of treatment-related EPS ([Arango et al. 2007](#); [Kudla et al. 2007](#)). Both active-comparator studies and medication-switching studies suggest that ziprasidone is associated with fewer EPS than risperidone ([Addington et al. 2003, 2009](#); [Weiden et al. 2003a, 2003b](#)) or FGAs ([Hirsch et al. 2002](#); [Weiden et al. 2003a, 2003b](#)). A direct comparison study of ziprasidone and olanzapine, a drug with intrinsic antimuscarinic activity

as well as 5-HT<sub>2</sub> receptor antagonist activity, reported that treatment with olanzapine was associated with fewer EPS ([Kinon et al. 2006](#)), whereas two other direct comparison studies ([Breier et al. 2005](#); [Simpson et al. 2002](#)) and one medication-switching study ([Weiden et al. 2003b](#)) reported that the two drugs exhibited similar liability for EPS. With respect to akathisia, one comparison study indicated that less akathisia occurs with olanzapine use ([Breier et al. 2005](#)), whereas another study noted no difference in akathisia rates with olanzapine versus ziprasidone ([Kinon et al. 2006](#)). Results from phase 1 and phase 2 of the large-scale CATIE study suggested no significant differences among ziprasidone, perphenazine, olanzapine, quetiapine, and risperidone in the incidence of EPS and akathisia ([Lieberman 2007](#); [Lieberman et al. 2005](#); [Stroup et al. 2006](#)). However, the perphenazine arm in the CATIE study was restricted to patients who did not already have tardive dyskinesia, suggesting a possible selection bias toward patients less likely to experience EPS. Despite this advantage, the perphenazine group still had the highest rate of dropouts due to EPS. Investigating SGAs only, a recent meta-analysis ([Rummel-Kluge et al. 2012](#)) of 54 comparative clinical trials analyzed the use of antiparkinsonian medication as an indicator of treatment-related EPS. The authors reported that risperidone was associated with greater use of antiparkinsonian medication compared with clozapine, olanzapine, quetiapine, or ziprasidone. Ziprasidone was associated with more use of antiparkinsonian medication than olanzapine or quetiapine; however, the authors concluded that overall differences were small. EUFEST data ([Rybakowski et al. 2014](#)) suggest that in first-episode schizophrenia patients during the first year of antipsychotic treatment (including quetiapine), EPS

were present at low and manageable levels. More recently, SGAs in patients never exposed to FGAs have been examined for their tardive movement disorder liability ([Ryu et al. 2015](#)). Although the incidence of movement disorder symptoms was low, the authors found that the median interval between the first exposure to the antipsychotic and movement syndrome onset was 15 months for tardive dyskinesia and 43 months for tardive dystonia.

Intramuscular ziprasidone has been tolerated at dosages of up to 80 mg/day with a low liability for EPS ([Daniel 2003](#); [Daniel et al. 2001](#); [Lesem et al. 2001](#)). Both intramuscular ziprasidone use and sequential intramuscular/oral ziprasidone use are associated with a lower incidence of treatment-related movement disorders than intramuscular haloperidol use ([Swift et al. 1998](#); [Zimbroff et al. 2002](#)) and sequential intramuscular/oral haloperidol use ([Brook et al. 2000](#), [2005](#)). Although the results of controlled experimental studies indicate a generally low risk of EPS with ziprasidone, there have been uncontrolled observational reports of EPS-related adverse events co-occurring with ziprasidone treatment and, in many cases, concomitant treatment with other agents ([Dew and Hughes 2004](#); [Duggal 2007](#); [Keck et al. 2004](#); [Mason et al. 2005](#); [Papapetropoulos et al. 2005](#); [Ramos et al. 2003](#); [Rosenfield et al. 2007](#); [Weinstein et al. 2006](#); [Yumru et al. 2006](#); [Ziegenbein et al. 2003](#)).

## **Metabolic Adverse Effects**

Adverse medication effects on modifiable risk factors for cardiovascular disease and type 2 diabetes mellitus have become an important topic of clinical, research, and regulatory concern, based in part on the increased prevalence of these conditions and associated premature

mortality in patients with major mental disorders ([Brown 1997](#); [Brown et al. 2000](#); [Colton and Manderscheid 2006](#); [Harris and Barraclough 1998](#); [Hennekens et al. 2005](#); [Joukamaa et al. 2001](#); [Osby et al. 2000, 2001](#)). Modifiable cardiometabolic risk factors include obesity, hyperglycemia, dyslipidemia, hypertension, and smoking—all prevalent conditions in patients with major mental disorders, with substantial evidence that primary and secondary prevention approaches are underutilized in these patients ([Allison et al. 1999a](#); [Brown et al. 2000](#); [Druss and Rosenheck 1998](#); [Druss et al. 2000, 2001](#); [Frayne et al. 2005](#); [Hippisley-Cox et al. 2007](#); [McEvoy et al. 2005](#); [Nasrallah et al. 2006](#); [Newcomer and Hennekens 2007](#)). In particular, use of recommended monitoring of changes in weight and in plasma glucose and lipid levels during antipsychotic treatment has heightened interest in cardiometabolic risk effects that may go undetected during the course of treatment ([American Diabetes Association 2004](#); [Morrato et al. 2008](#)). All currently available antipsychotic medications are associated with a risk of weight gain, as well as potential adverse effects on plasma glucose and lipid levels, although there is substantial variability in the magnitude of these effects across individual agents ([Casey et al. 2004](#); [Eli Lilly 2008](#); [Newcomer 2005](#); [Schizophrenia.com 2007](#)). Potential adverse treatment effects on body weight can increase the risk for cardiovascular disease and type 2 diabetes, commonly via adiposity-related increases in insulin resistance, dyslipidemia, and hyperglycemia ([Fontaine et al. 2001](#); [Haupt et al. 2007](#); [Koro et al. 2002a, 2002b](#)).

Treatment with ziprasidone is associated with a relatively low risk of clinically significant increases in body weight. An analysis of available studies with this agent and other

antipsychotics, both FGAs and SGAs ([Allison et al. 1999b](#)), estimated a mean 0.04-kg weight gain over a 10-week treatment period with ziprasidone, identifying ziprasidone as having one of the lowest estimated effects on body weight of those analyzed. In a 6-week RCT in patients with acute exacerbations of schizophrenia or schizoaffective disorder, treatment with ziprasidone 80 mg/day produced a median increase in body weight of 1 kg, compared with no change in median weight with ziprasidone 160 mg/day or placebo ([Daniel et al. 1999](#)). In a 28-week study of outpatients with schizophrenia, mean changes in body weight from baseline to endpoint were similar during treatment with ziprasidone (+0.31 kg) and haloperidol (+0.22 kg) ([Hirsch et al. 2002](#)). In a 28-week study comparing the effects of ziprasidone and olanzapine, ziprasidone-treated patients experienced a small decrease in mean body weight (−1.12 kg) compared with a statistically and clinically different 3.06-kg mean increase in body weight observed with olanzapine treatment ([Hardy et al. 2003](#); [Kinon et al. 2006](#)). Reductions in body weight were also associated with ziprasidone treatment in the 1-year ZEUS study of patients with chronic, stable schizophrenia ([Arato et al. 2002](#)); this study reported mean decreases from baseline of 2.7 kg, 3.2 kg, and 2.9 kg with 40 mg/day, 80 mg/day, and 160 mg/day dosages of ziprasidone, respectively, compared with a 3.6-kg decrease observed with placebo treatment. Results from the phase 1 and phase 2 CATIE studies provide further confirmation that treatment with ziprasidone has a low intrinsic risk for producing clinically significant weight gain, with 6%–7% of ziprasidone recipients demonstrating a 7% or greater increase from baseline body weight compared with, for example, 27%–30% of olanzapine recipients ([Lieberman](#)

2007; Stroup et al. 2006). In the phase 1 CATIE study, ziprasidone treatment was associated with a mean reduction in body weight of 0.14 kg (0.3 lb) per month of treatment, compared with a mean increase of 0.91, 0.23, and 0.18 kg per month (2.0, 0.5, and 0.4 lb per month, respectively) during treatment with olanzapine, quetiapine, and risperidone, respectively, the other SGAs tested (Lieberman et al. 2005). A recent meta-analysis of pooled data from nine placebo-controlled RCTs suggested no significant differences in weight gain between patients treated with ziprasidone versus those receiving placebo (Gao et al. 2013).

It is important to note that initial courses of treatment can clearly be associated with greater weight gain than subsequent courses of treatment (McEvoy et al. 2007). In addition, chronically treated patients switching treatment from a medication with greater weight gain liability to a medication with less weight gain liability are likely to lose body weight in relation to that medication change, an effect that likely underlies the mean reductions in weight noted in some of the trials with ziprasidone discussed above. The magnitude of change in body weight during treatment with ziprasidone varies as a function of the weight gain liability of the prior treatment: the greatest potential for weight loss is associated with switching from previous treatments with the greatest weight gain liability (Weiden et al. 2008). For example, 6 weeks of ziprasidone therapy was associated with statistically significant decreases in mean body weight from baseline in patients switched from olanzapine (−1.8 kg) and from risperidone (−0.9 kg), whereas patients switched from high-potency FGAs such as haloperidol experienced a small increase in weight (+0.3 kg) (Weiden et al. 2008). The 1-year extension of this medication-

switching study indicated that weight loss was progressive and persistent throughout the 1-year period for patients who switched from olanzapine (−9.8 kg, or 10.3% of baseline body weight) and from risperidone (−6.9 kg, or 7.8% of baseline) (Figure 30-4; Weiden et al. 2008). Another study found significant decreases in weight in patients treated for 6 months with ziprasidone who were switched from olanzapine (−7.0 kg) and from risperidone (−2.2 kg) (Montes et al. 2007).

**FIGURE 30-4.** Time course of weight change over 58 weeks after switching to ziprasidone.

Previous treatments were conventional antipsychotics (line with circles;  $n=71$ ), risperidone (line with squares;  $n=43$ ), or olanzapine (line with triangles;  $n=71$ ). Individual observed cases within each treatment group are also shown (circle=conventional agent:

baseline weight, 198 lbs [90 kg]; square=risperidone: baseline weight, 194.9 lbs [88.6 kg]; triangle=olanzapine: baseline weight, 210.3 lbs [95.6 kg]). LS=least-squares analysis; MMRM=mixed-model repeated-measures analysis; OC=observed case analysis.

\* $P < 0.01$  versus baseline (MMRM and OC).

*Source.* Adapted from [Weiden et al. 2008](#), Figure 1 (p. 988).

Ziprasidone's effects on plasma glucose and lipid levels are best understood as being a function of treatment-related changes in adiposity. Whereas some antipsychotics, such as clozapine and olanzapine, have been reported to produce adiposity-independent effects on insulin sensitivity and related changes in glucose and lipid metabolism, ziprasidone has demonstrated no similar adiposity-independent effects in this same experimental paradigm ([Houseknecht et al. 2007](#)). In general, increases in adiposity are associated with decreases in insulin sensitivity in individuals taking or not taking antipsychotic medications, with reduced insulin sensitivity leading to increased risk for hyperglycemia, dyslipidemia, and other adverse changes in cardiometabolic risk indicators ([Haupt et al. 2007](#); [Newcomer and Haupt 2006](#); [Strassnig et al. 2015](#)).

Both short- and long-term studies have shown minimal adverse effects of ziprasidone on glucose levels, plasma insulin levels, insulin resistance, or fasting and nonfasting lipid levels ([Daniel et al. 1999](#); [Glick et al. 2001](#); [Rettenbacher et al. 2006](#); [Simpson et al. 2004a, 2005](#)), in contrast to the degree of adverse effects detected with some active comparators. For example, olanzapine treatment can produce statistically significant increases in fasting glucose and insulin levels ([Glick et al. 2001](#); [Hardy et al. 2003](#); [Simpson et al. 2002, 2005](#)). In the CATIE phase 1 study, ziprasidone treatment was associated with minimal

drug exposure-adjusted mean increases in blood glucose ( $+2.9 \pm 3.4$  mg/dL) and hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>) ( $+0.11 \pm 0.09\%$ ) and decreases in plasma triglycerides ( $-16.5 \pm 12.2$  mg/dL) and total cholesterol ( $-8.2 \pm 3.2$  mg/dL) ([Lieberman 2007](#)). In the CATIE phase 2 study, ziprasidone-treated patients showed minimal drug exposure-adjusted mean increases in blood glucose ( $+0.8 \pm 5.6$  mg/dL) and HbA<sub>1c</sub> ( $+0.46 \pm 0.3\%$ ) and decreases in triglycerides ( $-3.5 \pm 20.9$  mg/dL) and total cholesterol ( $-10.7 \pm 5.1$  mg/dL) ([Stroup et al. 2006](#)).

Similar to the effect of prior treatment conditions on changes in weight during treatment with ziprasidone, improvements in plasma lipid levels observed during ziprasidone treatment in the CATIE study can best be understood as the effect of switching from a previous treatment that is associated with larger adverse effects on lipid metabolism to a treatment with minimal adverse effects. [Weiden et al. \(2003a\)](#) noted that ziprasidone treatment was associated with significant decreases from baseline in both median nonfasting triglyceride levels and median nonfasting total cholesterol levels at the end of the 6-week treatment period in patients whose prior medication was olanzapine or risperidone, with minimal change following prior treatment with high-potency FGAs like haloperidol. Notably, the reductions in lipids observed during this study occurred within the first 6 weeks of initiating treatment with ziprasidone, with substantial reductions in total cholesterol ( $>20$  mg/dL) and plasma triglycerides (78 mg/dL) in the patients previously treated with olanzapine. In the 12-month extension of this study, the reductions achieved in the initial weeks following the switch from prior treatment were sustained during continued treatment with ziprasidone ([Weiden et al. 2008](#)).

## Cardiac Effects and Risks

Some medications, including psychotropic medications, can increase the duration of the QTc interval (i.e., the QT interval corrected for heart rate). Basic research suggests plausible mechanisms by which an increase in the QTc interval could increase the risk of sudden cardiac death, and clinical investigations suggest that certain small subgroups of the general population may have an increased risk of sudden cardiac death—for example, those with a family history of congenital long-QT syndrome (>500 msec) and those who concomitantly use drugs that markedly increase the QTc interval (e.g., by >60 msec) via either pharmacokinetic or pharmacodynamic interactions ([Montanez et al. 2004](#)). These potential risks have understandably led to regulatory interest in drug effects on the QTc interval. It should be noted that epidemiological studies in the general population suggest that modest prolongations of the QTc interval are not a risk factor for cardiovascular mortality or sudden death, so any risk in the general population of modest QTc prolongations is likely to be small and difficult to detect reliably ([Montanez et al. 2004](#)). When considered alongside risks such as obesity, hypercholesterolemia, diabetes, hypertension, physical inactivity, or cigarette smoking, each with well-characterized effects in the general population, modest QTc prolongations do not represent a comparable risk factor for cardiovascular mortality or sudden death in the general population.

With this background, thioridazine, following decades of use, was required to add to its prescribing information a black box warning related to its QTc interval-prolonging effects. Other FGAs, including haloperidol, are also

associated with some risk of QTc interval prolongation (Gury et al. 2000; O'Brien et al. 1999). The rate of occurrence of torsades de pointes with FGAs has been estimated as "10–15 such events in 10,000 person-years of observation" (Glassman and Bigger 2001, p. 1774). Ziprasidone, in common with certain other antipsychotic agents, can induce orthostatic hypotension, particularly early in treatment exposure, which can lead to transient tachycardia, dizziness, or syncope (Swainston Harrison and Scott 2006). However, tachycardia has been observed to be infrequent and to be as common in patients treated with placebo as in those treated with ziprasidone (Swainston Harrison and Scott 2006). Tachycardia and syncope related to hypotension are to be distinguished from ventricular arrhythmias that in rare cases can occur in relation to QTc interval prolongation.

Ziprasidone treatment has been demonstrated to result in a modestly increased risk of QTc interval prolongation (Pfizer Inc. 2008). This QTc interval prolongation at  $C_{max}$  (mean increase, >15 msec) is 9–14 msec greater than that seen with risperidone, olanzapine, quetiapine, or haloperidol but approximately 14 msec less than that seen with thioridazine. Unlike the case with thioridazine, the modest effect of ziprasidone on the QTc interval is not worsened by the presence of commonly encountered inhibitors of drug metabolism. In clinical trials of ziprasidone monotherapy that reported QTc interval changes, in studies of high-dosage intramuscular administration (Miceli et al. 2010), and in case reports of ziprasidone overdose, there was no evidence of any significant clinical sequelae such as torsades de pointes or sudden death (Arato et al. 2002; Arbuck 2005; Daniel 2003; Gómez-Criado et al. 2005; Harrigan et al. 2004; Insa

Gómez and Gutiérrez Casares 2005; Levy et al. 2004; Lieberman 2007; Miceli et al. 2004; Montanez et al. 2004; Nemeroff et al. 2005; Tan et al. 2009; Taylor 2003; Weiden et al. 2002, 2003a). These findings are consistent with analyses of large population samples, which have failed to demonstrate any association between QTc interval duration and either cardiovascular or all-cause mortality (Goldberg et al. 1991).

The Ziprasidone Observational Study of Cardiac Outcomes (ZODIAC) was a large (>18,000 participants) international randomized trial designed to examine the risks of nonsuicide mortality and hospitalization associated with ziprasidone's use in routine medical practice settings (Strom et al. 2011). The main objective of ZODIAC was to evaluate nonsuicide mortality in the year following treatment initiation, which limited the study's ability to provide data on drug efficacy. Nevertheless, findings did not show an elevated risk of nonsuicide mortality for ziprasidone relative to olanzapine, and the study excluded a relative risk larger than 1.39 with a high probability. A total of 205 deaths occurred in the overall study population (N=18,154). It should be noted that ZODIAC was not designed to measure electrocardiographic parameters or to examine the risk of rare cardiac events associated with lengthening of the QTc interval. A recent meta-analysis evaluating the cardiac safety of antipsychotics in pediatric patients (Jensen et al. 2015) found a mean increase in QTc interval of 8.74 ms with ziprasidone. Compared with placebo, none of the tested antipsychotics caused a significant increase in the incidence of QTc prolongation, although there was significant reporting bias. The authors concluded that individual risk factors need to be taken into

account when evaluating medication-related QTc interval changes.

Rare cases of torsades de pointes have been reported with a number of different medications, including ziprasidone, but the incidence of these events appears to be below the known prevalence of torsades de pointes in community-based population samples ([Heinrich et al. 2006](#)). The USPI suggests that clinicians should nonetheless be cognizant of this potential risk and be aware of circumstances that may increase the risk of torsades de pointes and/or sudden death in association with the use of any drugs that can prolong the QTc interval. Such circumstances include bradycardia, hypokalemia, or hypomagnesemia; concomitant use of other medications known to cause clinically significant QT prolongation (although an additive effect with ziprasidone has not been established); and presence of congenital long-QT syndrome. The USPI further states that ziprasidone should not be used in patients who have significant cardiovascular conditions, such as uncompensated heart failure or a cardiac arrhythmia, or in those who have had a recent acute myocardial infarction or persistent QTc interval measurements of greater than 500 msec, and the prudent clinician might consider employing the same caution with many other antipsychotic and psychotropic medications currently in use. A comprehensive review of the cardiac safety of antipsychotics ([Hasnain and Vieweg 2014](#)) reached a similar conclusion—that little evidence exists that antipsychotic drug-associated QTc interval prolongation is in itself sufficient to cause torsades de pointes in the absence of other factors that facilitate or attenuate progression of drug-associated QTc interval prolongation to torsades de pointes.

---

## Drug-Drug Interactions

---

A study of in vitro enzyme inhibition ([Pfizer Inc. 2008](#)) indicated that ziprasidone has very little inhibitory effect on CYP1A2, CYP2C9, CYP2C19, CYP2D6, and CYP3A4 and is thus unlikely to interfere with the metabolism of other medications relying on these enzymes for clearance. In vivo studies indicated that ziprasidone has no effect on the pharmacokinetics of lithium, estrogen, progesterone, or dextromethorphan ([Pfizer Inc. 2008](#)). As noted earlier (in the “Metabolism and Elimination” subsection), less than one-third of ziprasidone clearance is mediated by CYP-catalyzed oxidation, and because of this, one would not anticipate a substantial change in ziprasidone AUC during coadministration with CYP3A4 inhibitors or inducers. Aldehyde oxidase-mediated reduction constitutes the primary metabolic pathway for ziprasidone. As also noted above, currently no clinically significant pharmacological inhibitors of aldehyde oxidase are commonly encountered ([Obach et al. 2004](#)).

Consistent with this prediction, coadministration of ziprasidone with ketoconazole, a potent CYP3A4 inhibitor, results in only a modest increase in ziprasidone AUC (33%) and  $C_{\max}$  (34%) ([Miceli et al. 2000b](#)), whereas coadministration with carbamazepine, an inducer of 3A4, results in modest reductions in ziprasidone AUC (44%) and  $C_{\max}$  (39%) ([Miceli et al. 2000a](#)). Coadministration with CYP2D6 inhibitors has no effect on ziprasidone plasma levels. Coadministration of ziprasidone with lithium results in no significant change in steady-state lithium levels ([Apseloff et al. 2000](#)), and commonly used antacids and

cimetidine do not significantly alter ziprasidone pharmacokinetics ([Pfizer Inc. 2008](#)).

---

## Conclusion

---

Ziprasidone was the fourth atypical antipsychotic following clozapine to become available in the United States. This agent has a unique pharmacological profile, with the highest 5-HT<sub>2A</sub>/D<sub>2</sub> affinity ratio among currently available agents, potent serotonin and norepinephrine reuptake inhibition activity, agonist activity at 5-HT<sub>1A</sub> receptors, and clinically relevant antagonist activity at various 5-HT<sub>2</sub> receptor subtypes. Ziprasidone has demonstrated rapid-onset and sustained efficacy for the treatment of schizophrenia, schizoaffective disorder, and bipolar mania, with promising evidence of favorable mood, cognitive, and prosocial effects. It is also available in an intramuscular formulation for the treatment of acute agitated psychoses, and it was approved for the use of bipolar mania in children and adolescents 10–17 years of age.

Ziprasidone has highly favorable safety and tolerability profiles with limited potential for drug–drug and drug–disease interactions—critical issues for a patient population that generally has a high burden of medical comorbidity and is commonly exposed to complex polypharmacy. The adverse-effect profile of ziprasidone is particularly noteworthy in areas that are key to safety and tolerability in patients with major mental disorders such as schizophrenia and bipolar disorder, including low drug-related risk for acute EPS and minimal effects on cardiometabolic risk factors such as obesity and dyslipidemia.

# CHAPTER 31

## Asenapine

Leslie L. Citrome, M.D., M.P.H.

---

### History and Discovery

---

Asenapine as a sublingual tablet was initially approved by the U.S. Food and Drug Administration (FDA) in August 2009 for the treatment of acute schizophrenia and acute manic or mixed episodes associated with bipolar I disorder in adults. It was subsequently approved for maintenance treatment of schizophrenia in adults, for adjunctive use with lithium or valproate in the treatment of acute manic or mixed episodes associated with bipolar I disorder in adults, and for bipolar mania in pediatric patients (ages 10–17 years) as a monotherapy ([Actavis 2015](#)). In addition to the original unflavored formulation, a black cherry-flavored version of asenapine was brought to the U.S. market in 2010.

---

## Pharmacological Profile

---

Asenapine is a second-generation (atypical) antipsychotic that belongs to the chemical class of dibenzo-oxepino pyrroles (Figure 31-1). Its receptor-binding profile is notable for high affinity ( $K_i$  [values in nM]) for several 5-hydroxytryptamine (5-HT; serotonin) receptor subtypes, including 5-HT<sub>2C</sub> (0.03), 5-HT<sub>2A</sub> (0.06), 5-HT<sub>7</sub> (0.13), 5-HT<sub>2B</sub> (0.16), and 5-HT<sub>6</sub> (0.25), and for several dopamine receptor subtypes, including D<sub>3</sub> (0.42), D<sub>2</sub> (1.3), D<sub>1</sub> (1.4), and D<sub>4</sub> (1.1) (Actavis 2015; Shahid et al. 2009). Asenapine also has high binding affinities to histamine H<sub>1</sub> (1.0) and to norepinephrine  $\alpha_1$  (1.2) and  $\alpha_2$  (1.2) receptors. Asenapine binds with somewhat lower affinity to serotonin 5-HT<sub>5</sub> (1.6), 5-HT<sub>1A</sub> (2.5), and 5-HT<sub>1B</sub> (4.0) receptors and histamine H<sub>2</sub> (6.2) receptors. Asenapine very weakly binds to muscarinic M<sub>1</sub> (8,128) receptors. Asenapine acts as an antagonist at all of the above receptors.

---

**FIGURE 31-1.** Chemical structure of asenapine.

Asenapine has approximately 38 metabolites, none of them highly prevalent; these metabolites have little clinically relevant effects either because of their lower

affinity for the relevant receptors or because of their inability to cross the blood-brain barrier ([Citrome 2009, 2014a](#); [U.S. Food and Drug Administration 2009](#)). Although the precise mechanism of action of asenapine in the treatment of schizophrenia is unknown, it is thought that antagonism at the dopamine D<sub>2</sub> and serotonin 5-HT<sub>2A</sub> receptors mediates the drug's antipsychotic activity ([Actavis 2015](#)). In studies using positron emission tomography, asenapine has demonstrated dose-dependent dopamine D<sub>2</sub> receptor occupancy (dose range 0.1–4.8 mg), with a significant correlation between D<sub>2</sub> occupancy and plasma concentration ([U.S. Food and Drug Administration 2009](#)); sublingual administration of 4.8 mg twice daily resulted in a mean D<sub>2</sub> occupancy of 79% approximately 3–6 hours after dosing.

---

## Pharmacokinetics and Drug-Drug Interactions

---

Asenapine is the only commercially available antipsychotic that is absorbed primarily in the oral mucosa. It is formulated as a highly porous, rapid-dissolving tablet for sublingual administration, with a resulting bioavailability of approximately 35% ([Schering-Plough Research Institute 2009](#); [U.S. Food and Drug Administration 2009](#)). If the tablet is swallowed rather than allowed to orally dissolve, the drug's bioavailability is reduced to less than 2% because of high hepato-gastrointestinal first-pass metabolism ([Actavis 2015](#); [U.S. Food and Drug Administration 2009](#)). Patient instructions are to place the

tablet under the tongue and to refrain from eating or drinking for 10 minutes after administration, because drinking water sooner than 10 minutes can result in reduced bioavailability of asenapine ([Actavis 2015](#)).

Although asenapine was developed for sublingual administration, absorption will occur even if the tablet is placed elsewhere in the oral cavity, as was demonstrated in a study of healthy men who received single 5-mg doses of asenapine via sublingual, supralingual, and buccal routes ([Gerrits et al. 2010](#)). Drug exposure with buccal administration (i.e., “cheeking”) as measured by plasma levels was almost 25% higher than that with sublingual administration, whereas exposure with supralingual administration was 6% lower. However, these differences in exposure by oral administration site are small in relation to the wide variability in asenapine’s pharmacokinetics observed across the clinical studies used to obtain regulatory approval, where overall exposure varied by 37%, with a mean inter-individual variability of 26% and a mean intra-individual variability of 26% ([U.S. Food and Drug Administration 2009](#)). Doubling the dosage from 5 mg to 10 mg twice daily results in less than linear (1.7 times) increases in both the extent of exposure and the maximum concentration ([Actavis 2015](#)).

Peak plasma levels occur 30–90 minutes after administration, and asenapine has a mean terminal half-life of approximately 24 hours ([Actavis 2015](#); [Schering-Plough Research Institute 2009](#); [U.S. Food and Drug Administration 2009](#)). Barring any tolerability issues when starting treatment with asenapine, once-daily dosing in the evening is feasible given the half-life; however, the clinical trials supporting the approval of asenapine were conducted

using bid (twice-daily) dosing, resulting in the recommendation for bid dosing in product labeling.

Asenapine is metabolized in the liver primarily through direct glucuronidation by UGT1A4 and oxidative metabolism by cytochrome P450 (CYP) isoenzymes (predominantly CYP1A2). Asenapine has a large volume of distribution and is highly bound (95%) to plasma proteins, including albumin and  $\alpha_1$ -acid glycoprotein. Despite the fact that smoking can induce CYP1A2, concomitant smoking had no substantial effect on the pharmacokinetics of asenapine when tested in healthy male subjects ([U.S. Food and Drug Administration 2009](#)). Fluvoxamine, a potent CYP1A2 inhibitor, can increase exposure to asenapine by 29% and therefore should be coadministered with caution ([Actavis 2015](#)).

Use of asenapine is not recommended in patients with severe hepatic impairment (Child-Pugh class C); asenapine exposures are on average 7 times higher in patients with severe impairment than in those with normal hepatic function. However, no dosage adjustment is required in patients with mild (Child-Pugh A) or moderate (Child-Pugh B) hepatic impairment. No dosage adjustment is required for patients with renal impairment.

Asenapine can inhibit CYP2D6, resulting in twofold increases in paroxetine concentrations ([U.S. Food and Drug Administration 2009](#)). The product label advises caution when coadministering asenapine with drugs that are both substrates and inhibitors of CYP2D6 ([Actavis 2015](#)).

---

## Indications and Efficacy

---

# Approved Indications

Asenapine's efficacy in acute schizophrenia in adults was tested in four pivotal short-term randomized, double-blind, placebo- and active comparator-controlled multicenter studies ([Citrome 2011b, 2014b](#)). Two studies were accepted by the FDA as supportive of asenapine's efficacy in the acute treatment of schizophrenia in adults ([Kane et al. 2010](#); [Potkin et al. 2007](#)). Asenapine's efficacy in the treatment of manic or mixed episodes of bipolar I disorder in adults was supported in both of two completed Phase III randomized, placebo- and active comparator-controlled 3-week trials ([McIntyre et al. 2009a, 2010a](#)). Approximately 1 year after the initial approval of asenapine for these indications, the FDA approved asenapine for the maintenance treatment of schizophrenia (based on a double-blind, placebo-controlled multicenter clinical trial [[Kane et al. 2011](#)]) and for use as adjunctive therapy with either lithium or valproate in the acute treatment of manic or mixed episodes associated with bipolar I disorder (again based on a placebo-controlled trial [[Szegedi et al. 2012](#)]). Approval of asenapine for the treatment of bipolar mania in pediatric patients (ages 10–17 years) was obtained in 2015 based on a placebo-controlled trial ([Findling et al. 2015b](#)).

In adults, the recommended dosage of asenapine for acute schizophrenia is 5 mg bid; that for bipolar manic or mixed episodes is 10 mg bid (5 mg bid if administered with lithium or valproate), based on the clinical trials used to obtain regulatory approval. Titration to these target dosages is not necessary. In a modeling and simulation study ([Friberg et al. 2009](#)), asenapine dosages of 5 and 10 mg bid had similar efficacy in the acute treatment of schizophrenia. In the maintenance study in schizophrenia

on which asenapine's approval for that indication was based, the most commonly used dosage was 10 mg bid ([Kane et al. 2011](#)).

In pediatric patients (ages 10–17 years) with bipolar mania, the recommended starting dosage of asenapine as monotherapy is 2.5 mg bid, with increases up to 10 mg bid possible.

## Schizophrenia

### Short-Term Efficacy

In one of the two positive trials, 458 patients with acute schizophrenia were randomly assigned to fixed-dosage treatment with asenapine at 5 mg bid, asenapine at 10 mg bid, placebo, or an active control for assay sensitivity (haloperidol at 4 mg bid) for 6 weeks ([Kane et al. 2010](#)). The primary efficacy endpoint was change from baseline in the Positive and Negative Syndrome Scale (PANSS; [Kay et al. 1987](#)) total score. On analyses of change in PANSS total score, asenapine at 5 mg bid and haloperidol were both superior to placebo, with statistically significant differences seen from day 21 onward. However, asenapine at 10 mg bid did not demonstrate an advantage over placebo, a finding that the authors suggested may have been due in part to the high placebo response rate in this trial. Rates of response—defined as a minimum reduction of 30% in the PANSS total score or a Clinical Global Impression-Improvement (CGI-I) score of 1 (very much improved) or 2 (much improved)—were 55% for asenapine 5 mg bid, 49% for asenapine 10 mg bid, 43% for haloperidol, and 33% for placebo, yielding numbers needed to treat (NNTs) ([Citrome 2008](#)) versus placebo of 5 for asenapine 5 mg bid, 7 for

asenapine 10 mg bid, and 10 for haloperidol ([Citrome 2011b](#)).

In the second short-term acute schizophrenia trial that was considered positive and supportive of asenapine's efficacy, 182 patients were randomly assigned to asenapine 5 mg bid, placebo, or an active control for assay sensitivity (risperidone 3 mg bid) for 6 weeks ([Potkin et al. 2007](#)). The primary efficacy endpoint was change from baseline in the PANSS total score. Compared with placebo, asenapine produced significantly greater decreases in PANSS total scores from week 2 onward. Risperidone did not statistically significantly separate from placebo. Using the criterion of reduction in the PANSS total score of at least 30%, 38% of the patients in the asenapine group were categorized as responders, compared with 39% of those in the risperidone group and 25% of those in the placebo group, yielding NNTs versus placebo of 8 for asenapine and 7 for risperidone ([Citrome 2011b](#)).

Two other 6-week acute schizophrenia trials were conducted ([Citrome 2011b](#); [U.S. Food and Drug Administration 2009](#)). One trial was considered negative because asenapine at 5 or 10 mg bid failed to separate from placebo, whereas the active control (olanzapine at 15 mg/day) did separate from placebo. The other trial was considered a failed trial because neither asenapine at 5 or 10 mg bid nor the active control (olanzapine 10–20 mg/day) separated from placebo. An additional double-blind trial was conducted in Asian patients where 532 adult participants from Japan, Korea, and Taiwan were randomly assigned to receive asenapine 5 mg bid, 10 mg bid, or placebo for 6 weeks ([Kinoshita et al. 2016](#)). The primary efficacy endpoint was change from baseline on the PANSS total score. Improvements from baseline on PANSS total

scores were significantly greater in the patients receiving asenapine 5 mg bid or 10 mg bid, compared with those receiving placebo, from days 14 and 7, respectively. Using the criterion of reduction in PANSS total score of at least 30%, 39% of the patients in the asenapine 5 mg bid group and 44% of those in the 10 mg bid group were categorized as responders, compared with 21% of those in the placebo group, yielding NNTs versus placebo of 6 for asenapine 5 mg bid and 5 for asenapine 10 mg bid.

An 8-week, placebo-controlled, double-blind trial in 306 adolescent (ages 12–17 years) patients with schizophrenia failed to demonstrate asenapine's efficacy at dosages of 2.5 and 5 mg twice daily ([Findling et al. 2015a](#)).

## **Longer-Term Efficacy**

Asenapine's longer-term efficacy in schizophrenia was examined in a published 1-year double-blind study in 1,225 patients with schizophrenia or schizoaffective disorder. Patients were randomly assigned to receive asenapine (5 mg bid for the first week and then flexible dosing of 5 or 10 mg bid) or olanzapine (10 mg/day for the first week and then flexible dosing of 10 or 20 mg/day) ([Schoemaker et al. 2010](#)). There was no placebo arm. Rates of discontinuation because of insufficient therapeutic effect were 25.1% for asenapine and 14.5% for olanzapine (NNT=10 for olanzapine versus asenapine to avoid discontinuation because of insufficient therapeutic effect). Changes from baseline in PANSS total score were similar for asenapine and olanzapine at week 6 but showed a statistically significant difference in favor of olanzapine at endpoint (last observation carried forward). Among the patients who completed the entire year-long trial, changes in PANSS total score were similar for asenapine and olanzapine at

week 6 and also at week 52. Completers were eligible to participate in an extension study in which clinical stability was further demonstrated ([Schoemaker et al. 2012](#)).

Asenapine's efficacy in the maintenance phase of schizophrenia was demonstrated in a published 26-week double-blind, placebo-controlled multicenter clinical trial ([Kane et al. 2011](#)). Patients were randomly assigned either to continue receiving asenapine or to receive placebo after establishing stability on asenapine during the 26 weeks of open-label treatment immediately prior. Of the 700 enrolled patients who were treated with open-label asenapine, 386 met stability criteria and entered the double-blind phase. Times to relapse/impending relapse and to discontinuation for any reason were significantly longer with asenapine than with placebo. The incidence of relapse or impending relapse was 12.1% for asenapine and 47.4% for placebo (NNT=3). Completion rates were 69.6% for asenapine and 37.5% for placebo (NNT=4). The most commonly used dosage of asenapine was 10 mg bid in both the open-label and the double-blind phases.

In two randomized, double-blind 26-week studies and their respective 26-week extensions, [Buchanan et al. \(2012\)](#) tested the hypothesis that asenapine is superior to olanzapine for persistent negative symptoms of schizophrenia and assessed the comparative long-term efficacy and safety of the two agents. Approximately 1,000 subjects participated. In the two core studies, 26-week completion rates with asenapine were 64.7% and 49.6%, versus 80.4% and 63.8%, respectively, with olanzapine. In the two extension studies, completion rates were 84.3% and 66.3% with asenapine versus 89.0% and 80.9%, respectively, with olanzapine. Asenapine was not superior to olanzapine in change in the 16-item Negative Symptom

Assessment Scale total score in either core study, but asenapine was superior to olanzapine at week 52 in one of the extension studies. Weight gain was consistently lower with asenapine. Extrapyramidal side effect (EPS)-related adverse-event incidence was higher with asenapine, but Extrapyramidal Symptom Rating Scale-Abbreviated total score changes did not differ significantly between treatments.

## Bipolar Disorder

In two identically designed 3-week acute studies of asenapine in the treatment of bipolar manic or mixed episodes ([McIntyre et al. 2009a](#), [2010a](#)), 977 subjects were randomly assigned to receive flexibly dosed asenapine 5–10 mg bid (starting dosage 10 mg bid), olanzapine 5–20 mg/day (starting dosage 15 mg/day), or placebo. The primary outcome measure for each of these studies was change from baseline in the Young Mania Rating Scale (YMRS; [Young et al. 1978](#)) total score. In the first study ([McIntyre et al. 2009a](#)), YMRS total scores were statistically significantly improved from baseline to day 21 for asenapine and olanzapine compared with placebo. Sustained statistically significant improvement in the YMRS score compared with placebo was noted for asenapine and olanzapine from day 2 onward. Percentages of subjects meeting criteria for response (50% decrease from baseline YMRS total score) and remission (YMRS total score  $\leq 12$ ) were higher with asenapine (42.3% and 40.2%, respectively) than with placebo (25.2% and 22.3%, respectively), yielding NNTs for response and for remission

versus placebo of 6. The NNT for response for olanzapine versus placebo was 5, and that for remission was 6.

In the second study ([McIntyre et al. 2010a](#)), YMRS total scores also were statistically significantly improved from baseline to day 21 for asenapine and olanzapine compared with placebo, with sustained statistically significant improvement in the YMRS total score versus placebo noted for asenapine and olanzapine from day 2 onward. In post hoc analyses, changes in YMRS total scores from baseline to day 21 were significantly greater for olanzapine than for asenapine with last observation carried forward analysis, but not with mixed model for repeated measures analysis. Rates of response (42.6%) and remission (35.5%) with asenapine did not differ significantly from those with placebo (34% and 30.9%, respectively), yielding NNTs of 12 and 22, respectively. Olanzapine was superior to placebo in rates of response (54.7%) and remission (46.3%), with NNTs for olanzapine versus placebo of 5 and 7, respectively, and for olanzapine versus asenapine of 9 and 10, respectively. Based on the above studies, the recommended starting dose of asenapine monotherapy for acute bipolar mania or mixed episodes in adults is 10 mg bid. However, additional information is available from a 3-week, double-blind, placebo-controlled, fixed-dose study of asenapine 5 mg bid and 10 mg bid in adults with an acute bipolar I disorder manic or mixed episode ([Landbloom et al. 2016](#)). Both asenapine doses were statistically superior to placebo in mean change from baseline to day 21 in YMRS total score, suggesting that 5 mg bid can be an adequate dose for adults with acute bipolar mania or mixed episodes. However, in this trial, neither asenapine dose had significantly more YMRS responders or remitters at day 21 than placebo.

Asenapine's longer-term efficacy in patients with manic or mixed episodes of bipolar disorder was assessed in a 9-week extension ([McIntyre et al. 2009b](#)) to the original two pivotal studies ([McIntyre et al. 2009a, 2010a](#)), followed by an additional 40-week extension ([McIntyre et al. 2010b](#)). A total of 504 subjects received at least one dose of double-blind trial medication during the 9-week extension trial and included 181 subjects who were treated with asenapine and 229 who were treated with olanzapine from the feeder trials (and who continued on the same treatment in the extension). In addition, 94 subjects who were treated with placebo in the feeder trials were blindly allocated to receive asenapine 5–10 mg bid in the extension trial. The primary efficacy analysis demonstrated that asenapine was statistically noninferior to olanzapine as measured by the YMRS total score from baseline to day 84 for the observed case subjects who had 3 weeks of previous exposure to study medication. The proportions of participants who were YMRS responders and remitters were similar in the asenapine and olanzapine groups: the rates of response at last observation carried forward endpoint were 77% and 82% with asenapine and olanzapine, respectively, and the rates of remission were 75% and 79%, respectively. For the 218 patients who were subsequently enrolled for another 40 weeks of double-blinded treatment, maintenance of efficacy was observed for both asenapine and olanzapine, with no differences in response or remission rates between the two agents.

Another study tested the efficacy of asenapine 5 mg bid in the treatment of an acute manic or mixed episode when combined with lithium or divalproex over 12 weeks ([Szegedi et al. 2012](#)), and its findings supported this indication as approved by the FDA ([Actavis 2015](#)).

Adjunctive asenapine significantly improved mania versus placebo at week 3 (primary endpoint) and weeks 2–12. The YMRS response rates were similar at week 3 but significantly better with asenapine at week 12. The YMRS remission rates and changes from baseline on the Clinical Global Impression–Bipolar (CGI-BP) for mania and overall illness were significantly better with asenapine at weeks 3 and 12. Patients completing the core study were eligible for a 40-week double-blind extension assessing safety and tolerability ([Szegedi et al. 2012](#)).

Asenapine's efficacy in the treatment of acute mania in pediatric patients (ages 10–17 years) was established in a single 3-week placebo-controlled, double-blind trial of 403 patients, of whom 302 received asenapine at fixed dosages of 2.5 mg, 5 mg, and 10 mg bid ([Findling et al. 2015b](#)). All patients were started on 2.5 mg bid, and dosages were titrated upward every 3 days in a stepwise fashion for patients randomly assigned to receive the higher dosages. Asenapine was statistically superior to placebo in improving YMRS total scores and CGI-BP severity of illness scores. YMRS responder rates were 42%, 54%, and 52% for asenapine 2.5 mg, 5 mg, and 10 mg bid, respectively, versus 28% for placebo, yielding corresponding NNT values for asenapine versus placebo of 8, 4, and 5.

## Agitation

Although asenapine is not approved for this indication, it was tested for the management of agitation in a randomized controlled trial ([Pratts et al. 2014](#)). Adults ages 18–65 years ( $N=120$ , any diagnosis) manifesting agitation in an emergency department and found to have a score of

$\geq 14$  on the PANSS-Excited Component (PANSS-EC) were randomly assigned to receive either a single sublingual 10-mg tablet of asenapine or matching placebo. Changes in PANSS-EC score at 2 hours were statistically significantly greater for the asenapine-treated subjects compared with the placebo-treated subjects, with an effect noted at 15 minutes, the earliest time point at which outcome was measured. The NNT value for response versus placebo was 3, an effect size comparable to that observed in prior studies of intramuscular antipsychotics. This study awaits replication.

---

## Side Effects and Toxicology

---

Common adverse reactions with asenapine observed in short-term trials (incidence  $\geq 5\%$  and twofold greater than placebo) were akathisia, oral hypoesthesia (numbness), and somnolence for adult patients with schizophrenia; somnolence, dizziness, EPS other than akathisia, and increased weight for monotherapy in adult patients with bipolar manic or mixed episodes; and somnolence and oral hypoesthesia for adjunctive therapy in adult patients with bipolar manic or mixed episodes ([Actavis 2015](#)). Among pediatric patients with bipolar disorder, common adverse reactions observed with asenapine as monotherapy were somnolence, dizziness, dysgeusia, oral paresthesias, nausea, increased appetite, fatigue, and increased weight ([Actavis 2015](#)).

Somnolence is the single most common adverse event associated with asenapine treatment. The product label describes this effect as usually transient, with the highest

incidence reported during the first week of treatment ([Actavis 2015](#)). The highest rates of somnolence in adults were observed in the short-term acute manic/mixed-episode bipolar trials (most common dosage=10 mg bid), where somnolence was reported in 24% of patients receiving asenapine versus 6% of patients receiving placebo, for a number needed to harm (NNH) of 6; rates of reported somnolence in the short-term schizophrenia trials (dosage=5 or 10 mg bid) were 13% for asenapine versus 7% for placebo, yielding a NNH of 17 ([Citrome 2009](#)). Comparisons of other antipsychotics against placebo on the outcome of somnolence in short-term acute trials of schizophrenia yielded a broad range of incidence rates, resulting in NNH values that ranged from 7 for olanzapine or quetiapine extended-release to a non-statistically significant 42 for paliperidone ([Citrome and Nasrallah 2012](#)). Although somnolence was frequently reported, somnolence/sedation led to discontinuation in only a small proportion (0.6%) of adult patients treated with asenapine ([Actavis 2015](#)).

Dizziness can also occur and is attributable to asenapine's  $\alpha_1$ -adrenergic antagonist activity; however, rates of syncope were observed to be low among patients in contrast to rates observed among healthy volunteers in the clinical pharmacology trials ([U.S. Food and Drug Administration 2009](#)). Asenapine has a dose-related association with EPS and akathisia, although the frequency of these events is substantially lower with asenapine than with haloperidol ([Citrome 2009](#)).

Unique to asenapine is the possibility of oral hypoesthesia, spontaneously reported as an adverse reaction in about 5% of the participants with acute schizophrenia in the clinical trials ([Actavis 2015](#)). Directly

asking patients about oral hypoesthesia may yield higher rates of this adverse effect, as was observed in a study that examined the effect of absorption site on the pharmacokinetics of asenapine in healthy male subjects ([Gerrits et al. 2010](#)). In this study, reported rates of oral paresthesias were 75.8%, 55.9%, and 45.7% for the sublingual, supralingual, and buccal absorption sites, respectively.

Asenapine has a mild effect on QTc interval, similar to that seen with quetiapine ([Chapel et al. 2009, 2011](#)). Hypersensitivity reactions have been reported with asenapine, in some cases occurring after the first dose, and this risk is now highlighted in product labeling ([Actavis 2015](#)). Asenapine's effects on prolactin levels in the short-term schizophrenia and bipolar manic/mixed-episode studies in adults revealed no clinically relevant changes.

In the 6-week acute schizophrenia trials, clinically relevant weight gain ( $\geq 7\%$  over baseline body weight) was observed in 4.9% of subjects receiving asenapine versus 2% of those receiving placebo. In the 3-week acute bipolar manic/mixed-episode studies, clinically relevant weight gain was observed in 5.8% of subjects receiving asenapine versus 0.5% of those receiving placebo. In addition to a favorable weight-gain profile, asenapine has shown minimal effects on glucose-related laboratory parameters such as fasting glucose and fasting insulin ([Schering-Plough Research Institute 2009](#)).

Of interest are longer-term safety and tolerability comparisons of asenapine with other antipsychotics. In a 1-year double-blind, randomized controlled trial comparing asenapine with olanzapine ([Schoemaker et al. 2010](#)), the incidence of treatment-emergent adverse events was 82% in both groups. Mean weight gain was 0.9 kg with

asenapine and 4.2 kg with olanzapine. The proportion of patients experiencing clinically relevant weight gain ( $\geq 7\%$  over baseline) was approximately 35% for olanzapine and approximately 15% for asenapine (olanzapine versus asenapine, NNH=5). No notable changes or between-group differences were seen in measures of total cholesterol or glucose, but triglyceride levels rose substantially with olanzapine and declined slightly with asenapine. In the 2-year blinded extension study ([Schoemaker et al. 2012](#)), mean body weight during the extension did not change beyond the weight gain in the core study. In the core study, EPS reported as adverse events were more common with asenapine (18%) than with olanzapine (8%) (asenapine versus olanzapine, NNH=10). The most commonly reported type of movement disorder in the asenapine and olanzapine groups was akathisia, with treatment-emergent rates of 10% for asenapine and 4% for olanzapine (asenapine versus olanzapine, NNH=17). In the 2-year blinded extension study, incidence rates of EPS-related adverse events that started during the extension were lower for both asenapine (4.5%) and olanzapine (3.3%) compared with those that started during the core study. Not many new cases of akathisia were reported during the extension period. There was little change in EPS severity during the extension of treatment.

Safety and tolerability outcomes are available from a 40-week extension to the acute bipolar trials ([McIntyre et al. 2010b](#)), where clinically relevant weight gain occurred in 21.9%, 39.2%, and 55.1% of patients in the placebo/asenapine, asenapine, and olanzapine groups, respectively. The NNH for clinically relevant weight gain for olanzapine versus asenapine was 7. The percentage of patients shifting to above a prespecified akathisia global

rating scale threshold was higher in the asenapine group compared with the placebo/asenapine and olanzapine groups.

Tolerability of asenapine in the pediatric patients (ages 10–17 years) in the 3-week bipolar mania trial differed from that in the adult trials in terms of higher reported rates of somnolence, oral paresthesias (oral hypoesthesia, oral paresthesia, and oral dysesthesia), and weight gain ([Actavis 2015](#)). Rates of somnolence were 49% for asenapine (all dosages) versus 12% for placebo, yielding an NNH of 3, with no clear dose-response relationship. Rates of fatigue were substantially lower (9% and 5% for asenapine and placebo, respectively), but with a dose-response effect and a rate of 14% for subjects receiving asenapine 10 mg bid. Rates of oral paresthesias were 27% for asenapine (all dosages) versus 4% for placebo, yielding an NNH of 5. The proportions of patients experiencing clinically relevant weight gain ( $\geq 7\%$  over baseline body weight) were 12%, 8.9%, and 8% for asenapine 2.5 mg bid, 5 mg bid, and 10 mg bid, respectively, versus 1.1% for placebo, yielding corresponding NNH values of 10, 13, and 15. A 50-week open-label, flexible-dose extension trial was available for those who completed the 3-week acute trial ([Findling et al. 2016](#)). Among the tolerability variables of interest, combined somnolence/sedation/hypersomnia occurred most frequently (42.4%). In total, 34.8% of the participants experienced clinically significant weight gain.

---

## Conclusion

---

Asenapine's efficacy is evidenced both in short-term acute clinical trials and in longer-term studies. In the mind of the clinician, asenapine will likely be measured against other "metabolically friendly" second-generation antipsychotics such as ziprasidone, aripiprazole, iloperidone, lurasidone, brexpiprazole, and cariprazine, as well as newer agents in the antipsychotic development pipeline ([Citrome 2011a, 2013, 2015](#)). Differences among these choices include dosing factors (daily versus twice-daily dosing, the need for dosage titration, special requirements for administration with or without food) as well as specific side-effect profiles.

Asenapine is unique in being the only antipsychotic that is absorbed primarily in the oral mucosa. Nonadherence by "cheeking" becomes moot. The possibility of oral hypoesthesia and dysgeusia (distorted or bad taste), a medication effect likely not experienced previously by the patient, necessitates advance warning.

In summary, asenapine's place in the treatment of schizophrenia and bipolar manic or mixed episodes is likely to be in patients for whom metabolic concerns are of import and in patients who would prefer a sublingual preparation. Substantial heterogeneity exists among the different antipsychotics and among individual patients ([Volavka and Citrome 2009](#)), so that asenapine has a legitimate place on a formulary.

Specific obstacles to the first-line use of asenapine are the recommendations for twice-daily versus once-daily administration and the recommendation to avoid food or liquids for 10 minutes after dosing. Cost may be a further impediment, given the availability of inexpensive generic versions of risperidone, quetiapine, ziprasidone, and olanzapine in the United States, as well as other generic second-generation antipsychotics in other countries.

## CHAPTER 32

### Iloperidone

Peter F. Buckley, M.D.

Adriana E. Foster, M.D.

Oliver Freudenreich, M.D.

Scott Van Sant, M.D.

---

#### History and Discovery

Iloperidone was approved by the U.S. Food and Drug Administration (FDA) in 2009 for the treatment of schizophrenia. It meets the now generally appreciated profile of second-generation antipsychotics (SGAs), in that it has a complex pharmacology (with a predilection for dopamine and serotonin antagonism) and little propensity for extrapyramidal side effects (EPS), as well as efficacy against key symptoms of schizophrenia, as shown in placebo-controlled clinical trials ([Rado and Janicak 2010](#); [Weiden 2012](#)). Iloperidone's efficacy has been demonstrated at a dosage range of 12–24 mg/day, with no clear advantage evident at higher dosages. To minimize the risk of dizziness and postural hypotension consequent to iloperidone's antagonism of noradrenergic  $\alpha_1$  receptors, it is recommended that the drug be initiated and titrated upward with caution. Clinical experience with iloperidone is accruing, as is comparative information for iloperidone in relation to other SGAs ([Potkin et al. 2013](#); [Rado and Janicak 2014](#); [Tarazi and Stahl 2012](#)). Additional clinical trials of iloperidone are ongoing (see [www.clinicaltrials.gov](http://www.clinicaltrials.gov)).

---

#### Structure-Activity Relations and Pharmacological Profile

Iloperidone is an SGA of the piperidiny-benzisoxazole class ([Figure 32-1](#)). Structurally similar benzisoxazole derivatives include risperidone and its metabolite paliperidone, as well as ziprasidone. Iloperidone's chemistry and specific binding profile across multiple neuroreceptors are complex ([Citrome 2010](#); [Kalkman et al. 2003](#)). In brief, similar to several other SGAs, iloperidone is a serotonin 2A (5-HT<sub>2A</sub>) and dopamine 2 (D<sub>2</sub>) receptor antagonist. It has strong affinity for dopamine D<sub>3</sub> receptors and a lesser (but still more pronounced compared with other SGAs) affinity for D<sub>4</sub> receptors. It also has affinity for both 5-HT<sub>6</sub> and 5-HT<sub>7</sub> receptors. Iloperidone is further distinguished by its antagonism of

noradrenergic  $\alpha_1$  receptors. The strength of iloperidone's  $\alpha_1$ -receptor affinity exceeds that of all other SGAs except clozapine. In contrast, iloperidone has low affinity for 5-HT<sub>1A</sub> and histamine H<sub>1</sub> receptors. Collectively, this receptor affinity constellation may account for iloperidone's adverse-effect attributes of postural hypotension risk, prolactin-elevating capacity, modest weight-gain propensity, and mild sedative effects.

**FIGURE 32-1.** Chemical structure of iloperidone.

## Pharmacokinetics and Disposition

Iloperidone is readily absorbed from the gastrointestinal tract and reaches peak plasma concentrations approximately 2 hours after ingestion. Its absorption is slowed by food, but its bioavailability is unaffected; thus, it can be given either with or without food.

Iloperidone is extensively metabolized by the cytochrome P450 (CYP) enzyme system, particularly the 3A4 and 2D6 isoenzymes. Iloperidone's average half-life in "regular" (extensive) CYP2D6 metabolizers is approximately 24 hours. Clinicians need to be cautious when prescribing iloperidone concurrently with agents that inhibit CYP2D6 and CYP3A4 enzymes, a category that includes several antidepressant medications. It has been shown that a statistically significantly greater proportion of iloperidone responders than of nonresponders have average plasma concentrations of  $\geq 5$  ng/mL. That being said, blood levels of iloperidone are not available for use in clinical practice (Weiden 2012).

Iloperidone is currently available only in tablet form. No liquid or short-term intramuscular formulations or long-acting injectable forms have been developed.

There is currently no clinical evidence that the dosage of iloperidone requires adjustment on the basis of age or gender, although it is noteworthy that the potential for postural hypotension may be markedly higher in the elderly. Clinical studies of iloperidone in schizophrenia did not include sufficient numbers of patients ages 65 years and older to determine whether older persons respond differently from younger adults. Among more than 3,000 patients treated with iloperidone in the early registration trials, only 25 patients (0.5%) were  $\geq 65$  years old, and there were no patients  $\geq 75$  years old. Iloperidone's safety and effectiveness in pediatric patients have not yet been well studied; therefore, the drug should not be prescribed in children or adolescents. Additionally, iloperidone's teratogenic risk is unknown. It is therefore advised that lactating women who are being treated with iloperidone refrain from breast-feeding their newborns. The most recent FDA recommendations regarding use of antipsychotics during pregnancy and the neonatal period also apply to iloperidone (see FDA MedWatch; [www.fda.gov/Safety/MedWatch](http://www.fda.gov/Safety/MedWatch)).

# Indications and Efficacy

Iloperidone is FDA approved for the acute treatment of schizophrenia. No other indications for iloperidone were under consideration by the FDA at the time of this writing. However, the clinical trials program for this drug now includes investigative studies in mood disorders that are currently ongoing (see [www.clinicaltrials.com](http://www.clinicaltrials.com)).

## Schizophrenia

### Pivotal Clinical Trials

Iloperidone's FDA approval for the treatment of schizophrenia was predominantly based on four short-term placebo-controlled trials, highlighted in [Table 32-1](#). In addition, two long-term trials have been published ([Cutler et al. 2013](#); [Kane et al. 2008](#)). These studies are described in the following paragraphs. A more complete review of drug development and initial trials in humans is provided elsewhere ([Citrome 2010](#); [Rado and Janicak 2014](#)).

**TABLE 32-1. Pivotal clinical trials of iloperidone efficacy in patients with schizophrenia or schizoaffective disorder**

\*Relapse=25% increase in PANSS-T scores; discontinuation due to lack of efficacy hospitalization, or CGI increase by 2 points.

[Potkin et al. \(2008\)](#) reviewed the 6-week double-blind period of the pivotal trials that evaluated iloperidone's efficacy in the treatment of schizophrenia. All of these trials included screening, an acute double-blind phase, and a long-term maintenance phase.

Study 1 enrolled patients ages 18-65 years with acute or subacute exacerbations of schizophrenia or schizoaffective disorder and with Positive and Negative Syndrome Scale (PANSS) scores of 60 or greater. One hundred twenty-one patients were randomly assigned to receive iloperidone 4 mg/day, 125 to iloperidone 8 mg/day, 124 to iloperidone 24 mg/day, 124 to haloperidol 15 mg/day, and 127 to placebo. After a screening and a 3-day placebo run-in period as well as a 7-day fixed-titration period, patients were placed on

study medication for 5 weeks. The primary objective was to determine the efficacy of iloperidone versus placebo. The primary efficacy variable was change in PANSS total score (PANSS-T) from baseline to endpoint (day 42 or last visit before discontinuation). Although PANSS-T scores improved significantly from baseline for the iloperidone 12 mg/day ( $P=0.047$ ) and the haloperidol ( $P<0.001$ ) groups, improvement for the combined iloperidone 8 mg/day and 12 mg/day group was not significantly different from that for the placebo group. The all-cause discontinuation rates were 57%, 64%, and 58% for iloperidone 4 mg/day, 8 mg/day, and 12 mg/day, respectively; 65% for haloperidol; and 69% for placebo (Potkin et al. 2008).

In Study 2, patients selected according to the same inclusion criteria used in Study 1 were randomly assigned to receive iloperidone 4–8 mg/day ( $n=53$ ; 52% discontinued the study before endpoint) or 10–16 mg/day ( $n=154$ ; 44% discontinued), risperidone 4–8 mg/day ( $n=153$ ; 42% discontinued), or placebo ( $n=156$ ; 60% discontinued). The primary objective was again to determine the efficacy of iloperidone versus placebo. Both dosage ranges of iloperidone resulted in significant symptom improvement (as measured by Brief Psychiatric Rating Scale [BPRS] scores) from baseline compared with placebo (Potkin et al. 2008).

In Study 3, patients selected according to the previously described criteria were randomly assigned to receive iloperidone 12–16 mg/day ( $n=244$ ; 46% discontinued) or 20–24 mg/day ( $n=145$ ; 41% discontinued), risperidone 6–8 mg/day ( $n=157$ ; 29% discontinued), or placebo ( $n=160$ ; 46% discontinued). In this study, the iloperidone 12–16 mg/day dosage failed to separate from placebo (Potkin et al. 2008).

A combined analysis of all three studies was performed to eliminate the impact of early discontinuations (i.e., those occurring in the initial 2 weeks of the studies, during which the drug reaches steady state). When the analysis was restricted to patients who had remained in double-blind treatment for at least 2 weeks ( $n=1,553$ ), it showed that each of the iloperidone dosage ranges (4–8, 10–16, and 20–24 mg/day) separated significantly from placebo (Potkin et al. 2008).

A 4-week double-blind study (Cutler et al. 2008) evaluated the efficacy of iloperidone 24 mg/day against that of placebo and of ziprasidone 160 mg/day in patients with an acute exacerbation of schizophrenia by measuring change from baseline in the PANSS-T score and the PANSS positive, negative, and general psychopathology scale scores; the Calgary Depression Scale for Schizophrenia (CDSS) score; and the Clinical Global Impression–Severity (CGI-S) score. Iloperidone significantly reduced PANSS-T scores at 4 weeks compared with placebo. Although both iloperidone and ziprasidone significantly improved negative and positive PANSS and CGI-S scores compared with placebo, none of the drugs improved PANSS general psychopathology scores significantly, nor did any drug affect CDSS scores.

Kane et al. (2008) conducted a long-term efficacy analysis using data from patients who had completed the 6-week double-blind phase of the three pivotal studies described above. Patients who had at least a 20% reduction in PANSS-T scores and a CGI score of less than 4 and who had received at least one dose of long-term-phase medication were randomly assigned to iloperidone or haloperidol for 48 weeks of double-blind maintenance treatment (mean dosage at endpoint=12.5 mg/day for both drugs). The primary efficacy variable was relapse (defined as an increase of 25% or greater on the PANSS score). Differences between the iloperidone group and the haloperidol group in time to relapse were not significant—63.6% of patients in both groups completed the long-term phase of the trial.

Cutler et al. (2013) reported on a 25-week open-label extension study. More than 58% of patients discontinued iloperidone. Overall improvement was seen in 80% of patients.

Weiden et al. (2014) reported on a 12-week trial in which schizophrenia patients who were taking risperidone, olanzapine, or aripiprazole but were experiencing problems with tolerability or efficacy were switched to iloperidone (up to 12 mg twice daily) via random assignment to either an immediate-cessation or a gradual-downtitration strategy. The results were similar across all groups, and the two switching strategies yielded comparable efficacy and tolerability.

## Pharmacogenetic Studies

Clinical trials of iloperidone sought to establish the drug's pharmacogenetic characteristics (Volpi et al. 2009a, 2009b) by exploring the relationship between iloperidone's efficacy and various candidate genes related to dopamine receptors, dopamine  $\beta$ -hydroxylase, the serotonin 1B (5-HT<sub>1B</sub>) receptor, and the ciliary neurotrophic factor (CNTF). CNTF is a cytokine in the interleukin-6 cytokine family that suppresses noradrenergic and serotonergic function (Galter and Unsicker 1999). A null mutation in the CNTF gene leads to a non-G/G rs1800169 genotype that cannot produce a functional protein and has been linked to an increased risk of psychosis (Thome et al. 1996). However, a meta-analysis involving more than 1,000 patients and a similar number of control subjects (Lin and Tsai 2004) found no association between *CNTF* and schizophrenia risk.

In a 4-week randomized, placebo-controlled study in 417 patients genotyped for *CNTF*, 279 received iloperidone and 138 received placebo (Lavedan et al. 2008). Iloperidone improved symptom scores significantly versus placebo in patients with an active *CNTF* gene, whereas patients with the *CNTF* null allele showed no greater response to iloperidone than to placebo.

In a whole-genome study of 407 patients from the same sample, of which 218 patients received iloperidone, six single-nucleotide polymorphisms (SNPs) associated with iloperidone efficacy were identified (Volpi et al. 2009b). The identified loci included SNPs of the neuronal PAS domain protein 3 gene (*NPAS3*); of the XK Kell blood group complex subunit-related family member 4 gene (*XKR4*); of the tenascin-R gene (*TNR*); of the glutamate receptor ionotropic AMPA 4 gene (*GRIA4*); of the glial cell line-derived neurotrophic factor receptor alpha 2 gene (*GFRA2*); and of the NUDT9P1 pseudogene located in the chromosomal region of the serotonin receptor 7 gene (*HTR7*). More than 75% of the iloperidone-treated patients in the group with the optimal genotype combinations showed a  $\geq 20\%$  symptom improvement, whereas only 37% of patients with other genotypes showed a  $\geq 20\%$  improvement.

Another whole-genome association study (Volpi et al. 2009a) was conducted in 183 patients with schizophrenia who received an electrocardiogram (ECG) on day 14 of treatment with iloperidone, after the drug had reached steady state. DNA polymorphisms associated with QT prolongation were found in six loci, including *CERKL*, thought to be part of the ceramide pathway; *SLCO3A1*, which encodes the organic anion-transporting polypeptide; various genes involved in myocardial infarction (*PALLD*), cardiac structure and function (*BRUNOL4*), and cardiac development (*NRG3*); and an SNP on *NUBPL* with unknown function. Each SNP defined two genotype groups associated with a low mean QT interval change or a higher mean QT interval prolongation.

Although these findings have attracted considerable interest from the field, pharmacogenomic approaches to drug optimization need to be tested further in larger studies before these findings can be of clinical use. Nevertheless, the incorporation of

pharmacogenetic testing into the regulatory registration trials of this drug represents an important new aspect of psychopharmacological drug development.

## Other Indications

Little information is available on the use of iloperidone in patients with first-episode psychosis. Similarly, there are no studies to inform the use of iloperidone in patients with treatment-refractory schizophrenia. There is no information on the efficacy or tolerability of iloperidone in patients with comorbid substance use disorders. Information on the use of iloperidone in other comorbid conditions and/or in other primary psychiatric and neuropsychiatric disorders is scant. Given the paucity of data to guide treatment, off-label use of this drug cannot be recommended.

## Side Effects and Toxicology

### Common Adverse Events in Early Studies

The safety of iloperidone in short-term studies was examined in a pooled analysis of the three 6-week Phase II studies in acute schizophrenia ( $N=1,943$ ) conducted between 1998 and 2002 (Potkin et al. 2008). A total of 1,912 patients received at least one dose of study medication and were included in this pooled analysis. The safety cohort included 440 patients on placebo, 463 on iloperidone 4–8 mg/day, 456 on iloperidone 10–16 mg/day, 125 on iloperidone 20–24 mg/day, 118 on haloperidol 15 mg/day, and 306 on risperidone 4–8 mg/day. The most common treatment-related adverse events associated with iloperidone across all three dosage groups were dizziness, dry mouth, somnolence, and dyspepsia (Table 32-2).

**TABLE 32-2. Safety profile of iloperidone in short- and long-term studies: adverse events occurring in at least 5% of patients in any active-treatment group**

\*Did not occur in at least 5% of comparators.

<sup>a</sup>Pooled analysis of 6-week studies.

<sup>b</sup>Long-term (46 weeks) maintenance treatment (mean dosage 12.5 mg/day at study end for both drugs).

*Source.* Adapted from [Kane et al. 2008](#) and [Weiden et al. 2008](#).

With respect to available data from long-term studies, three prospective multicenter studies—each with a 6-week stabilization period followed by a 46-week double-blind maintenance phase—inform our understanding of iloperidone’s longer-term tolerability ([Kane et al. 2008](#); see [Table 32-2](#)). Patients were randomly assigned to receive iloperidone 4-16 mg/day or haloperidol 5-20 mg/day. Of the 1,644 patients who underwent random assignment and the 1,326 who completed the 6-week stabilization period, 473 (iloperidone 359, haloperidol 114) were included in the long-term efficacy analysis and 489 (iloperidone 371, haloperidol 118) were included in the safety analysis. The most common adverse events reported for iloperidone were insomnia, anxiety, and headache.

## Extrapyramidal Side Effects

In the pooled analysis of pivotal short-term trials comparing iloperidone (4-8 mg/day, 10-16 mg/day, and 20-24 mg/day), risperidone, and haloperidol, all iloperidone dosages demonstrated significant improvement (as measured by overall EPS ratings from baseline

to endpoint on the Extrapyramidal Symptom Rating Scale [ESRS]; [Chouinard and Margolese 2005](#)). By comparison, there was no significant change with risperidone and significant worsening with haloperidol. Akathisia items on the ESRS all showed significant improvement from baseline for iloperidone at the 10–16 mg/day and 20–24 mg/day dosage ranges ([Weiden et al. 2008](#)). The low EPS profile of iloperidone is an advantage clinically, even in this era of predominantly SGA prescribing in which one's risk of EPS is much lower than heretofore ([Weiden 2012](#)). Moreover, the absence of a dose-related increase in EPS across dosage ranges in clinical trials of iloperidone is conspicuous and encouraging.

## Orthostatic Hypotension

In view of its antagonism at  $\alpha_1$ -noradrenergic receptors, iloperidone possesses the potential for autonomic side effects. In its clinical trials program, iloperidone was associated with decreases in supine and standing systolic and diastolic blood pressures in all dosage groups. Decreases in blood pressure were mostly observed within the first week of treatment and were generally not sustained. Orthostatic hypotension was observed more frequently in all active-treatment groups (iloperidone, risperidone, and haloperidol) than in the placebo group. Sustained orthostatic hypotension was observed in 0.4% ( $n=2$ ), 3.8% ( $n=17$ ), and 4.8% ( $n=6$ ) of patients receiving iloperidone 4–8 mg/day, 10–16 mg/day, and 20–24 mg/day, respectively. According to the manufacturer's full prescribing information ([Vanda Pharmaceuticals 2016](#)), iloperidone must be initiated slowly and gradually so as to avoid orthostatic hypotension, with a starting dosage of 1 mg twice daily, increasing to 2 mg, 4 mg, 6 mg, 8 mg, 10 mg, and 12 mg twice daily on days 2, 3, 4, 5, 6, and 7, respectively, to a target dosage range of 12–24 mg/day. Clinicians should therefore pay particular attention to dizziness early in treatment with iloperidone. It is also important to go even slower with initial titration in patients who may be at risk for postural hypotension ([Weiden 2012](#)).

## Weight Gain and Metabolic Effects

One of the potential advantages of iloperidone could be its profile with respect to metabolic issues and weight gain ([De Hert et al. 2012](#); [Tarazi and Stahl 2012](#)). Compared with patients receiving placebo, patients receiving iloperidone exhibited a small but statistically significant increase in weight across all dosages. For all patients completing the respective studies, the mean weight gain was 2.4 kg in each iloperidone dosing group. Clinically significant weight gain (defined as  $\geq 7\%$  increase in body weight from baseline) occurred in 12.3% of all iloperidone groups ([Weiden et al. 2008](#)). The majority of the weight gain occurred within the first 6 weeks of the studies (6.4%). Long-term treatment with iloperidone also produced slight increases in total cholesterol, triglycerides, and glucose levels ([Kane et al. 2008](#)). Increased prolactin levels were not observed in the pooled analysis of the three 6-week trials. The prescribing information ([Vanda Pharmaceuticals 2016](#)), however, emphasizes findings from the 4-week iloperidone versus ziprasidone versus placebo trial, in which 26% of subjects receiving iloperidone, versus 12% of those receiving placebo, exhibited elevated plasma prolactin levels. Thus, the relatively more favorable weight and metabolic profiles of iloperidone constitute a distinction that might guide the selection and use of iloperidone in particular patient groups ([Weiden 2012](#)).

On the other hand, in a provocative preclinical study in which rats were exposed to iloperidone, asenapine, or olanzapine ([Boyda et al. 2013](#)) the iloperidone-exposed rats developed glucose intolerance. In a 12-month head-to-head study of lurasidone and risperidone in 611 patients with schizophrenia, baseline rates of metabolic syndrome were similar for both groups (33% for lurasidone; 33% for risperidone), whereas after 12 months, the incidence of new-onset metabolic syndrome was 16% in lurasidone-treated patients and 27% in risperidone-treated patients ([Newcomer 2014](#)).

## QT Interval Prolongation

With respect to potentially life-threatening side effects, there was evidence of significant QT/QTc interval prolongation across all iloperidone groups in the drug's pivotal study program, and this potential drug effect was a focus of review by the FDA. Specifically, the least square mean changes in QTc intervals from baseline to endpoint in these studies were 2.9 msec, 3.9 msec, and 9.1 msec for iloperidone 4–8 mg/day, 10–16 mg/day, and 20–24 mg/day, respectively. It is noteworthy that no deaths or serious arrhythmias attributable to QT prolongation occurred in these studies ([Weiden 2012](#); [Weiden et al. 2008](#)). [Potkin et al. \(2013\)](#) examined the incidence of QTc prolongation in patients randomly assigned to receive iloperidone, quetiapine, or ziprasidone. To further test for metabolic inhibition, there was a period of coadministration of paroxetine and paroxetine plus ketoconazole. These conditions revealed QTc intervals of 60 mg or greater in approximately 10% of patients receiving iloperidone. However, no patients had clinical symptoms, and none had a QTc interval that reached or exceeded 500 mg.

## Contraindications

According to the manufacturer's prescribing information ([Vanda Pharmaceuticals 2016](#)), iloperidone should be avoided in combination with other drugs that are known to prolong the QTc interval, a group that includes Class Ia (e.g., quinidine, procainamide) and Class III (e.g., amiodarone, sotalol) antiarrhythmic medications, antipsychotic medications, and antibiotics. This prohibition makes sense, given iloperidone's metabolism through these cytochrome pathways. In addition, it is recommended that iloperidone be avoided in persons with congenital long-QT syndrome or cardiac arrhythmias.

In common with all other SGAs, iloperidone carries a black box warning regarding the increased mortality risk associated with use of antipsychotic drugs in elderly patients with dementia-related psychosis. That said, iloperidone is not approved for the treatment of patients with dementia-related psychosis, and use in the elderly should be avoided pending future clinical trials.

---

## Conclusion

---

Iloperidone is an FDA-approved antipsychotic with proven efficacy in the treatment of schizophrenia. There remains much to be studied regarding its use in specific subgroups of psychotic patients. Iloperidone's utility in nonapproved mood disorder indications is currently unknown. There is a need for additional dose-finding studies to guide the optimal use of this drug.

# CHAPTER 33

## Lurasidone

Philip D. Harvey, Ph.D.

**Lurasidone** (Latuda), one of the most recent additions to the atypical antipsychotic class, received U.S. Food and Drug Administration (FDA) approval for the treatment of schizophrenia in October 2010 and for the treatment of bipolar depression in June 2013. As with all currently registered antipsychotic medications, lurasidone is a dopamine D<sub>2</sub> receptor antagonist. In addition, this compound is a full antagonist at the serotonin 2A (5-HT<sub>2A</sub>) receptor, similar to other atypical antipsychotic medications. Lurasidone has other receptor affinities that may contribute to additional beneficial or adverse effects. Because lurasidone is relatively new, its database is limited compared with that of other medications, although the recently approved indication for bipolar depression has led to several additional publications. A current interesting line of investigation is lurasidone's potential utility in the treatment of a new entity defined in DSM-5 ([American](#)

[Psychiatric Association 2013](#)), bipolar depression with mixed features.

In this chapter, I review the pharmacological properties and efficacy basis of lurasidone, the side effects and adverse events from the pivotal studies, and other features of the compound that may prove to be important in later studies as well as in the clinical applications of this agent. I also consider the question of what, if anything, seems unique about lurasidone compared with other available antipsychotic medications.

---

## Pharmacological Properties

---

### Receptor-Binding Profile

Lurasidone belongs to the chemical class of benzisothiazole derivatives ([Figure 33-1](#)). The compound is a full antagonist at dopamine D<sub>2</sub> and serotonin 5-HT<sub>2A</sub> receptors, a profile it shares with other atypical antipsychotics. Lurasidone also has high affinity for 5-HT<sub>7</sub> receptors, with in vitro affinity for 5-HT<sub>7</sub> being relatively higher than that shown by the drug for D<sub>2</sub> and 5-HT<sub>2A</sub> receptors. Lurasidone is a partial agonist at 5-HT<sub>1A</sub> receptors ([Ishibashi et al. 2010](#)), and it has moderate affinity for noradrenergic receptors. Lurasidone's minimal affinity for α<sub>1</sub>-adrenergic receptors would be expected to convey a reduced risk for orthostatic hypotension in comparison with compounds that have higher affinity for this receptor. Lurasidone appears to have weak affinity for 5-HT<sub>2C</sub> receptors and no affinity for histamine H<sub>1</sub> receptors, a profile that should carry

relatively low risk for weight gain. Lurasidone lacks affinity for muscarinic acetylcholine M<sub>1</sub> receptors, which suggests reduced risk for cholinergic cognitive deficits and other side effects.

**FIGURE 33-1.** Chemical structure of lurasidone.

## Pharmacokinetics and Dosing

Lurasidone is rapidly absorbed and reaches peak concentrations within 3 hours for the lowest effective antipsychotic dose, 40 mg. Steady state is reached within 7 days ([Sunovion Pharmaceuticals 2013](#)). The molecule is metabolized in the liver via the cytochrome P450 (CYP) 3A4 enzyme system, leading to the conclusion that lurasidone should not be used in the presence of strong inducers (e.g., rifampin) or inhibitors (e.g., ketoconazole) of CYP3A4. Lurasidone does show a food effect. A study examining food effects on lurasidone concentrations found that taking the drug with meals containing 350 calories or more, with either low or high fat content, led to a doubling of the bioavailability of lurasidone compared with dosing during fasting ([Chiu et al. 2010](#)).

The recommended starting dosage of lurasidone is 40 mg/day taken concurrently with at least 350 calories of food. Dosages up to 160 mg/day are currently approved for schizophrenia and up to 120 mg/day for bipolar depression. As previously noted, lurasidone should not be used by patients taking medications that are strong metabolic inducers or inhibitors of CYP3A4. There are no suggested dosage adjustments based on age, gender, ethnicity, or smoking, but individuals with renal or hepatic impairment should not be prescribed dosages greater than 40 mg/day. Lurasidone is currently available in 20-, 40-, 80-, and 120-mg tablets ([Sunovion Pharmaceuticals 2013](#)).

Lurasidone lacks a requirement for initial dosage titration and appears to require minimal adjustment and tinkering. Having a starting dose with substantial efficacy is a strong point for many patients. Food effects are an issue, given that optimal exposure requires the medication to be taken with at least 350 calories of food (with no minimum fat content specified); however, the lack of a need for titration and the uncomplicated requirements for suitable meals will make it easier to apply this treatment to patients who may be challenged in their ability to adhere to complex regimens.

---

## **Efficacy and Tolerability**

---

### **Pivotal Registration Trials in Schizophrenia**

In the standard drug development program, lurasidone at daily dosages of 40 mg, 80 mg, and 120 mg was compared with placebo in four separate studies ([Meltzer et al. 2011](#); [Nakamura et al. 2009](#); [Nasrallah et al. 2013](#); [Ogasa et al. 2013](#)), with several different dosing and comparator strategies. A fifth study ([Loebel et al. 2013](#)) added a 160-mg/day dosage. [Citrome \(2011a, 2011b\)](#) reviewed data based on conference presentations for the schizophrenia development program. Patients ranged in age from 18 to 74 years and were symptomatic with an acute exacerbation of psychosis. In the early clinical studies, the dosage that most consistently separated from placebo was 80 mg/day, although 40 mg/day and 120 mg/day did as well in some trials. Lurasidone at 120 mg/day did not confer additional clinical benefit on the primary outcomes—improved scores on either the Positive and Negative Syndrome Scale (PANSS) or the Brief Psychiatric Rating Scale (BPRS)—across the different studies. However, clinical data submitted to the FDA led to an increase in the approved dosage to a maximum of 160 mg/day.

## Comparative Efficacy Studies

### Schizophrenia

Four blinded and randomized studies compared lurasidone with other agents in the treatment of schizophrenia.

In the first study ([Potkin et al. 2011](#)), lurasidone was compared with ziprasidone in a 3-week randomized trial in 301 patients with schizophrenia. Both treatments improved symptoms as measured by the PANSS, and there was no significant difference in endpoint PANSS scores.

In the second study ([Meltzer et al. 2011](#)), lurasidone was compared with olanzapine in clinically unstable patients with schizophrenia who had been admitted to inpatient care. Both olanzapine and lurasidone were superior to placebo for clinical response. In addition, the weight gain with olanzapine was significantly greater than that with either lurasidone or placebo, whereas rates of akathisia were significantly higher in the lurasidone group compared with the other two groups.

In the third study ([Loebel et al. 2013](#)), two dosages of lurasidone (80 and 160 mg/day) were compared with quetiapine extended release (XR) 600 mg/day and placebo in inpatients experiencing an acute exacerbation of schizophrenia. Both lurasidone (at both dosages) and quetiapine separated from placebo, and weight gain and sedation/sleepiness were more frequent with quetiapine than with either dosage of lurasidone.

In the fourth study ([Citrome et al. 2012](#)), clinically stable patients with schizophrenia were randomly assigned to receive either risperidone or lurasidone and were followed for 12 months to assess potential differences in long-term safety. Findings included greater weight gain with risperidone, minimal differences between lurasidone and risperidone in efficacy, and no differences between the two agents in relapse rates. All-cause discontinuation rates were higher for lurasidone, possibly due to slight elevations in nausea in the lurasidone group.

## **Bipolar Depression**

Two randomized placebo-controlled trials of lurasidone were conducted in patients with bipolar depression. In the first study ([Loebel et al. 2014a](#); monotherapy), lurasidone at two different dosage ranges (20–60 mg/day and 80–120

mg/day) was compared with placebo. Both dosage ranges separated from placebo, with similar effect sizes. In the second study ([Loebel et al. 2014b](#); adjunctive therapy), lurasidone at 20–120 mg/day was added to stable treatment with either valproate or lithium. Statistically significant separation from placebo was found. Lurasidone treatment was administered at a mean modal dose of 75 mg/day, which translates to an available dose of 80 mg/day. The results of these two studies led to lurasidone's approval by the FDA for both augmentation of lithium or valproate therapy and monotherapy of bipolar depression in June 2013.

In an additional post hoc analysis of the results of the monotherapy study, [McIntyre et al. \(2015\)](#) reported that lurasidone was effective in the treatment of bipolar depression with mixed features, an entity newly defined in DSM-5. The presence of mixed features was defined as having a Young Mania Rating Scale (YMRS; [Young et al. 1978](#)) score of 4 or greater. Fifty-six percent of the patients in the study were found to have mixed features (272 out of 485 patients). Of the patients with mixed features, 182 received treatment with active lurasidone and 90 received placebo treatment. Efficacy for the treatment of depression in patients with and without mixed features was essentially equivalent: 15.7-point decreases in Montgomery-Åsberg Depression Rating Scale (MADRS; [Montgomery and Åsberg 1979](#)) scores were seen for patients without mixed features, and 15.2-point decreases were found for those with mixed features. Eighty-two percent of the patients without mixed features completed the trial when treated with active lurasidone, and 73% of the patients with mixed features completed the study with active treatment. These data indicate that the presence of mixed features in bipolar

depression should not be viewed as a contraindication to treatment with lurasidone.

In a very recent study ([Suppes et al. 2016](#)), lurasidone was tested for efficacy in major depression with mixed features. This newly defined condition is characterized by the coexistence within a major depressive episode of a limited set of manic symptoms ([American Psychiatric Association 2013](#)). Patients selected for the presence of DSM-IV-TR ([American Psychiatric Association 2000](#))-defined major depressive disorder and two or three manic symptoms were randomly assigned to lurasidone ( $n=109$ ) or placebo ( $n=100$ ) for a 6-week trial. Lurasidone was superior to placebo, leading to a 20.5-point change on the MADRS for active treatment compared with a 13-point change for placebo ( $P<0.001$ ; effect size  $d=.80$ ). Completion rates were similar for active treatment and placebo (94% and 85%, respectively), and the remission rate was 49% for active treatment. Switch into mania did not occur with lurasidone treatment, and patients who received lurasidone manifested a 7-point decrease in their YMRS scores. These data suggest efficacy for lurasidone in the treatment of depression with mixed features as well as bipolar depression.

## Summary of Efficacy and Tolerability Data

The risk-benefit evaluation for lurasidone suggests a lower potential for metabolic consequences and QTc prolongation combined with a slightly higher risk of extrapyramidal side effects (EPS) and akathisia compared with some of the other atypical antipsychotic medications. Prolactin elevation

appears to be minimal within the approved dosage range. Given our limited clinical experience with lurasidone, it may be premature to target an optimal patient for this medication; however, the reduced metabolic consequences of lurasidone would seem to be a very strong point. Patients who are extraordinarily vulnerable to EPS may require close monitoring.

Lurasidone's efficacy in schizophrenia relative to other agents has been examined in four active comparison studies ([Citrome et al. 2012](#); [Loebel et al. 2013](#); [Meltzer et al. 2011](#); [Potkin et al. 2011](#)), none of which found lurasidone to be inferior. It is not yet possible to assess lurasidone's relative efficacy in bipolar depression, given the absence of comparative trials to date.

---

## Side Effects and Safety

---

### Class Warnings

The typical class warnings are present on the lurasidone label ([Sunovion Pharmaceuticals 2013](#)), including the black box warning about increased stroke risk in elderly individuals and a variety of other class warnings regarding neuroleptic malignant syndrome, tardive dyskinesia, diabetes, hyperlipidemia, weight gain, glucose abnormalities, hyperprolactinemia, agranulocytosis, suicide, and seizures. Lurasidone has no warning for QTc alteration; a dedicated cardiac safety study (referenced in the package insert) found no evidence of QTc prolongation with lurasidone treatment.

# Adverse-Event Reports

Safety information is available from the manufacturer's safety database (see also [www.sunovionprofile.com/sp/latuda-bp.html](http://www.sunovionprofile.com/sp/latuda-bp.html)). Dose-related adverse effects that separated from placebo included somnolence, akathisia, and EPS (as measured by total scores on clinical rating scales for EPS). Of note, weight and metabolic parameters were only minimally affected in patients with schizophrenia or bipolar depression in clinical trials. Although short-term changes in cholesterol, triglycerides, and glucose are likely to be attributable to transition from medications with more substantial adverse profiles in these domains, the weight-gain data for lurasidone are very noticeable and consistent.

---

## Promising Features

---

### Favorable Metabolic Profile

Lurasidone appears to have the promise of weight neutrality. Weight gain in the pooled 6-week studies across doses was 0.75 kg; in the pooled 12-month database from extension studies, patients lost an average of 0.4 kg ([Meyer et al. 2015](#)). These statistics compare favorably with those for other antipsychotics in wide clinical use (see review by [Citrome 2011b](#)). It is important to note that specific populations outside the current label may have a greater weight-gain risk compared with the typical patient with chronic schizophrenia in these trials. Data are not yet

available for lurasidone's profile in the long-term treatment of bipolar depression. Nevertheless, the suggestion of no weight gain after a year's treatment, even for patients who may have gained weight with previous treatments, is quite promising.

## Potential Cognitive Benefits

### Basic Science Rationale

Compounds that interact with the 5-HT<sub>7</sub> receptor as their primary binding profile have historically been shown to produce beneficial cognitive effects in animal models ([Ballaz et al. 2007](#)). Furthermore, it is postulated that agents with partial agonist properties at the 5-HT<sub>1A</sub> receptor may have potential benefit in regard to reduction of flat affect and related negative symptoms in schizophrenia ([Newman-Tancredi 2010](#)).

MK-801 is a glutamate receptor antagonist that is used to induce cognitive impairments in healthy individuals that are quite similar to those seen in schizophrenia. Like other *N*-methyl-D-aspartate (NMDA) antagonists, MK-801 is capable of inducing deficits in memory and problem solving. Given that NMDA antagonists such as ketamine and phencyclidine can induce a reliable analog of schizophrenia in healthy people (and exacerbate psychosis in patients with schizophrenia), such manipulations have more intrinsic validity than cholinergic manipulations such as scopolamine challenge. In rats, lurasidone has shown the potential to reverse MK-801-induced learning and memory deficits in the passive avoidance test ([Ishiyama et al. 2007](#)) and the Morris water maze ([Enomoto et al. 2008](#)).

Research using analogs of cognitive impairment derived from animal models has notoriously failed to yield paradigms with adequate translational relevance to the specific cognitive domains affected in schizophrenia, particularly in terms of reliably predicting beneficial cognitive effects associated with pharmacological treatment ([Harvey 2009](#)). A possible reason for this failure may be that the adverse influences on human cognition of dopamine D<sub>2</sub> receptor antagonism associated with antipsychotic treatment may override the influences of a “secondary” receptor profile, preventing its beneficial effects from being realized ([Harvey and McClure 2006](#)). For example, ziprasidone, a partial agonist at the 5-HT<sub>1A</sub> receptor, has never demonstrated greater cognitive benefit versus antipsychotics that do not interact with that receptor (e.g., olanzapine; [Harvey et al. 2004](#)). Thus, clear evidence of cognitive enhancement in patients with schizophrenia treated with the medication of interest, compared with other treatments in similar populations, is the “bottom line” requirement for demonstration of meaningful cognitive benefit.

## **Studies in Schizophrenia**

Three published studies in patients with schizophrenia have addressed the issue of lurasidone’s cognitive benefit compared with that of other antipsychotics ([Harvey et al. 2011, 2013, 2015](#)).

The first study, which was conducted during the early development phases of lurasidone, was a 3-week double-blind, randomized head-to-head comparison of lurasidone versus ziprasidone in generally clinically stable outpatients with schizophrenia ([Harvey et al. 2011](#)). At the time this

study was conducted, no U.S. patients had ever been exposed to lurasidone. Patients were selected for being naive to treatment with ziprasidone as well. The study examined changes in performance on a neuropsychological assessment consisting of most of the tests in the widely used Measurement and Treatment Research to Improve Cognition in Schizophrenia (MATRICS) Consensus Cognitive Battery (MCCB; [Nuechterlein et al. 2008](#)) and an interview-based assessment of cognitive functioning, the Schizophrenia Cognition Rating Scale (SCoRS; [Keefe et al. 2006](#)). The study found that lurasidone was associated with improvements on neuropsychological tests that were generally consistent with practice effects ([Harvey et al. 2011](#)). There was one exception, processing speed, which manifested relatively greater improvement with lurasidone than with ziprasidone. However, improvements seen with lurasidone on the SCoRS were double the size of improvements seen on the neuropsychological assessments and nearly significantly larger than the improvements associated with ziprasidone. These results cannot be attributed to practice effects, given that the SCoRS is an interview, not a performance-based measure. Furthermore, the fact that the differential effects of lurasidone and ziprasidone were nearly significant ( $P<0.06$ ) argues against a generalized bias effect, because the lurasidone effects were clearly larger.

The second study ([Harvey et al. 2013](#)) compared two dosages of lurasidone (80 and 160 mg/day) with 600 mg/day of quetiapine XR and placebo. This double-blind, placebo-controlled trial was conducted in patients experiencing an acute exacerbation of psychosis. Lurasidone 160 mg/day was compared with placebo, quetiapine XR, or lurasidone 80 mg/day over a 6-week

period, followed by a 6-month double-blind extension. Follow-ups were conducted at 3 and 6 months, and placebo patients were switched to lurasidone at flexible dosages; quetiapine XR patients remained on the same treatment. The CogState Computerized Cognitive Battery ([Pietrzak et al. 2009](#)) and the University of California San Diego (UCSD) Performance-based Skills Assessment—Brief version (UPSA-B; [Mausbach et al. 2007](#); [Patterson et al. 2001](#)) were administered at baseline and at each assessment point. When patients who provided invalid baseline CogState data were censored from the analysis, lurasidone at 160 mg/day separated from placebo on composite cognitive improvement at the 6-week endpoint, whereas lurasidone at 80 mg/day and quetiapine XR did not.

[Harvey et al. \(2015\)](#) presented an analysis of the dose-response relationships of lurasidone compared with quetiapine during the full 6-month duration of the trial. The full sample, regardless of the validity of baseline performance, was examined at two follow-up assessments (at 3 and 6 months). Both dosages of lurasidone were found to be superior to quetiapine XR at both assessments ([Harvey et al. 2015](#)). Scores on the UPSA-B improved with all active treatments at each of the assessment time points, with no between-group differences in improvements.

Although these results clearly require replication, they suggest that lurasidone may have beneficial cognitive effects. In all three studies, performance- and interview-based assessments of functionally relevant cognitive processes showed treatment-related improvements. In the [Harvey et al. \(2013\)](#) study, the performance-based cognitive assessments also showed improvements that were superior to those seen with placebo or the active comparator. This superiority to the comparator was confirmed across all

dosages of lurasidone in the [Harvey et al. \(2015\)](#) study. The sleepiness-inducing effects of quetiapine XR may have contributed to the difference between this compound and lurasidone ([Loebel et al. 2014c](#)); however, that circumstance would not have explained the separation of lurasidone from placebo.

---

## Conclusion

---

Lurasidone is a new antipsychotic with some benefits compared with other available medications, including low weight-gain propensity and reduced risk for metabolic side effects. Little of the published data have been supported by sources other than the sponsor of the medication. We will watch this medication carefully to continue to determine its benefit over time. Since the previous edition of this textbook, the indication for bipolar depression has been added and additional cognitive and long-term safety data have become available. No new safety concerns have emerged, and no new data raising efficacy questions have appeared.

# CHAPTER 34

## Cariprazine

Sultan Albrahim, M.D.

Joseph H. Henry, M.D.

Charles B. Nemeroff, M.D., Ph.D.

Cariprazine (Vraylar) was initially discovered by the Hungarian company Gedeon Richter Ltd. (November 2004) and was developed by Forest Laboratories and submitted to the U.S. Food and Drug Administration (FDA) in November 2012 ([Forest Laboratories 2012](#)). In September 2015, cariprazine was approved by the FDA for the treatment of schizophrenia and acute manic or mixed episodes associated with bipolar I disorder in adults ([Actavis Inc. 2015](#)) ([Figure 34-1](#)). Cariprazine is also in development in a variety of countries for use in the treatment of schizophrenia with predominantly negative symptoms (Phase III), for use as an adjunct in the treatment of major depressive disorder (Phase II/III), and for use in the treatment of bipolar depression (Phase II) ([McCormack 2015](#)).

---

**FIGURE 34-1.** Key development milestones for cariprazine.

Note. FDA=U.S. Food and Drug Administration; NDA=new drug application.

Source. Reprinted from McCormack PL: "Cariprazine: First Global Approval." *Drugs* 75(17):2035-2043, 2015. Copyright © 2015, Springer International Publishing. Used with permission.

Cariprazine, a piperazine/piperidine derivative, is classified as an atypical antipsychotic on the basis of its dopamine receptor partial agonist mechanism. Cariprazine is the third agent with a dopamine receptor partial agonist mechanism to become available (aripiprazole was approved in 2002, and brexpiprazole received FDA approval on July 13, 2015, both for schizophrenia; see [Chapter 29](#) in this volume, "Aripiprazole and Brexpiprazole," by Gonzalez and Strassnig). In common with aripiprazole and brexpiprazole, cariprazine has partial agonist effects at dopamine 2 ( $D_2$ ) and dopamine 3 ( $D_3$ ) receptors and serotonin 1A ( $5-HT_{1A}$ ) receptors and antagonist effects at serotonin 2A ( $5-HT_{2A}$ ) receptors. What is unique about cariprazine is its higher affinity for and more selective binding to  $D_3$  receptors compared with other currently marketed typical and atypical antipsychotics.

---

## Comparison With Other Dopamine Receptor Partial Agonists

---

The theory behind the use of partial agonists, including cariprazine, is that these agents restore homeostatic balance to neurochemical circuits by 1) decreasing the effects of endogenous neurotransmitters (dopamine tone) in regions of the brain where their transmission is excessive, such as in the mesolimbic regions in schizophrenia or mania; 2) simultaneously increasing neurotransmission in regions where transmission of endogenous neurotransmitters is low, such as in the prefrontal cortex in schizophrenia; and 3) exerting little effect in regions where neurotransmitter activity is normal, such as the pituitary gland.

Aripiprazole and brexpiprazole are dopamine  $D_2$  receptor-preferring partial agonists, with minimal  $D_3$  effects. In contrast, cariprazine has a six- to eightfold greater affinity for  $D_3$  receptors than for  $D_2$  receptors, with a specificity for the  $D_3$  receptor that is 3–10 times greater than aripiprazole's specificity for that receptor ([Mattingly and Anderson 2016](#)).

Aripiprazole binds more potently than cariprazine to human and rat  $5-HT_{2A}$ ,  $5-HT_{2C}$ , and adrenergic receptors. In contrast, cariprazine has lesser

affinity for human and rat hippocampal 5-HT<sub>1A</sub> receptors (and demonstrates low intrinsic efficacy), low affinity for human 5-HT<sub>2A</sub> receptors, moderate or low affinity for histamine H<sub>1</sub> and 5-HT<sub>2C</sub> receptors, and negligible affinity for cholinergic or adrenergic receptors, all of which suggest a reduced propensity for side effects related to these receptors (Kiss et al. 2010).

In addition to its labeled indications for schizophrenia and manic or mixed episodes associated with bipolar I disorder, aripiprazole is approved as an adjunctive treatment for depression or bipolar maintenance, and for irritability associated with autistic disorder. In addition to its approved use in schizophrenia, brexpiprazole has an FDA indication for use as an adjunct to antidepressant treatment in major depressive disorder. Cariprazine has not been directly compared with aripiprazole, brexpiprazole, or other antipsychotic agents in clinical studies of schizophrenia or bipolar I disorder, and it has not yet received approval for indications other than schizophrenia and bipolar I disorder. In contrast to the variety of formulations available for aripiprazole, cariprazine is currently available only in a capsule for oral administration.

Although their mechanisms of action are in some ways similar, the three agents differ in terms of their pharmacodynamic profile and receptor affinities, as summarized in Table 34-1.

**TABLE 34-1. Pharmacodynamic profiles of cariprazine, aripiprazole, and brexpiprazole: in vitro binding affinities for human receptors**

Receptor <sup>b</sup>		Activity	Affinity K <sub>i</sub> <sup>a</sup> (in vitro)		
			Cariprazine	Aripiprazole	Brexpiprazole
Dopamine	D <sub>3</sub>	Partial agonist	0.085	0.8	1.1

<sup>a</sup>Receptor binding affinity K<sub>i</sub> [nM], inverse relationship.

<sup>b</sup>Cariprazine and aripiprazole demonstrated negligible (percentage displacement less than 20% at 1 μM test concentration) affinities for adrenergic (α<sub>2B</sub>, α<sub>2C</sub>), cannabinoid (CB<sub>1</sub>, CB<sub>2</sub>), dopamine (D<sub>1</sub>, D<sub>4.2</sub>, D<sub>5</sub>), histamine (H<sub>2</sub>, H<sub>3</sub>, H<sub>4</sub>), muscarinic (M<sub>1</sub>, M<sub>2</sub>, M<sub>3</sub>, M<sub>4</sub>, M<sub>5</sub>), nicotinic, and serotonin (5-HT<sub>3</sub>, 5-HT<sub>4</sub>, 5-HT<sub>5A</sub>, 5-HT<sub>6</sub>) receptors (Kiss et al. 2010).

## Pharmacodynamics

### Structure

Cariprazine, also known as RGH-188 and MP-214, is 3-[4-{2-[4-(2,3-dichlorophenyl)piperazin-1-yl]ethyl} cyclohexyl]-1,1-dimethylurea ([Figure 34-2](#)). The active ingredient is cariprazine hydrochloride, a compound synthesized and selected for development on the basis of its high selectivity for dopamine D<sub>3</sub> receptors over D<sub>2</sub> receptors ([Veselinovic et al. 2013](#)).

Cariprazine has two clinically relevant active metabolites: desmethyl-cariprazine (DCAR) and didesmethyl-cariprazine (DDCAR) ([Citrome 2013b](#)).

**FIGURE 34-2.** Chemical structures of cariprazine and its major metabolites, desmethyl-cariprazine (DCAR) and didesmethyl-cariprazine (DDCAR).

## Receptor-Binding Profile

Cariprazine is a potent dopamine D<sub>3</sub> and D<sub>2</sub> receptor partial agonist with preferential binding to D<sub>3</sub> receptors, which is a unique pharmacological profile among known antipsychotic medications ([Kiss et al. 2010](#)).

Whereas D<sub>2</sub> receptor antagonism is required for antipsychotic efficacy, D<sub>3</sub> receptor antagonism may impart beneficial effects on cognition while attenuating the risk of extrapyramidal side effects (EPS) ([Veselinovic et al. 2013](#)).

Cariprazine acts as a partial agonist at dopamine D<sub>3</sub> and D<sub>2</sub> receptors with very high binding affinity and at serotonin 5-HT<sub>1A</sub> receptors with high binding affinity (see [Table 34-1](#)). Cariprazine acts as an antagonist at serotonin 5-HT<sub>2B</sub> and 5-HT<sub>2A</sub> receptors with very high and moderate binding affinity, respectively, and at histamine H<sub>1</sub> receptors with moderate binding affinity. Cariprazine shows weak binding affinity for serotonin 5-HT<sub>2C</sub> and 5-HT<sub>7</sub> receptors, very low affinity for  $\alpha_{1A}$ -adrenergic receptors,

and no appreciable affinity for cholinergic muscarinic receptors ([Actavis Inc. 2015](#)).

## Dopamine Receptors

**D<sub>3</sub> and D<sub>2</sub>.** Dopamine, the neurotransmitter primarily linked to psychosis, has very high affinity for D<sub>3</sub> receptors. In vitro, virtually all of the first- and second-generation antipsychotics in clinical use are D<sub>2</sub> nonselective and therefore show considerable affinity for the D<sub>3</sub> receptor subtype. D<sub>3</sub> receptors have pre- and postsynaptic localizations in brain stem nuclei, limbic parts of the striatum, and cortex and exert a widespread influence on dopamine release, on dopaminergic function, and on several other neurotransmitters. The D<sub>2</sub> receptor's assumed role as an autoreceptor is suggested by its high expression in regions such as the ventral tegmental area and substantia nigra.

The signaling pathways of D<sub>3</sub> receptors are distinct from those of other members of the D<sub>2</sub>-like receptor family. Although the role of D<sub>3</sub> receptor blockade in alleviating positive symptoms is still controversial, selective D<sub>3</sub> receptor antagonism has therapeutic effects in schizophrenia and beyond, as demonstrated by several animal models: improved cognitive function, emotional processing, executive function, flexibility, and social behavior. D<sub>3</sub> receptor antagonism seems to contribute to the atypicality of antipsychotics by reducing motor EPS; has no direct influence on prolactin release; and does not cause anhedonia, weight gain, or metabolic dysfunction ([Gross and Drescher 2012](#)).

D<sub>3</sub>, an autoreceptor primarily located in the limbic system, controls phasic (not tonic) activity of dopamine nerve cells and mediates behavioral abnormalities induced by glutamate and *N*-methyl-D-aspartate receptor antagonists ([Veselinovic et al. 2013](#)).

Animal models and preclinical studies have demonstrated antipsychotic-like and procognitive effects potentially attributable to dopamine D<sub>3</sub> receptor-preferring agents. D<sub>3</sub> receptor blockade appears to enhance—whereas D<sub>3</sub> receptor agonism seems to impair—cognitive function in animals ([Gyertyán et al. 2011](#)).

The overall function of dopamine D<sub>3</sub> receptors in the human brain remains incompletely understood.

## Serotonin Receptors

**5-HT<sub>1A</sub>.** Cariprazine has a high affinity for human serotonin 5-HT<sub>1A</sub> receptors and acts as a partial agonist at these receptors. The effect of cariprazine depends on the serotonin concentration at the site.

In vivo, at lower dosages, cariprazine's partial agonism at 5-HT<sub>1A</sub> receptors may contribute minimally to its antipsychotic-like activity and side-effect profile; at higher dosages, the 5-HT<sub>1A</sub> receptor partial agonism may contribute to cariprazine's favorable side-effect profile (i.e., lack of EPS) ([Kiss et al. 2010](#)).

Cariprazine's 5-HT<sub>1A</sub> receptor partial agonism may also contribute to its antidepressant efficacy ([Bluer and Ward 2003](#)) and to its beneficial effects on negative symptoms and cognitive dysfunction ([Bantick et al. 2001](#)), as suggested by preclinical studies.

**5-HT<sub>2B</sub>.** Cariprazine has very high binding affinity for human serotonin 5-HT<sub>2B</sub> receptors ( $K_i=0.58$  nM). Activity at these receptors may modulate dopamine release in the nucleus accumbens ([Citrome 2013a](#)).

Cariprazine's antagonist activity at 5-HT<sub>2B</sub> receptors may contribute to its postulated effects on mood and cognition, as observed in preclinical studies.

**5-HT<sub>2A</sub>.** Cariprazine's binding affinity for human serotonin 5-HT<sub>2A</sub> receptors is lower than that of aripiprazole and brexpiprazole. Theoretically, antagonist effects at serotonin 5-HT<sub>2A</sub> receptors are essential for "atypicality" of antipsychotics. It is unknown whether cariprazine's relatively low affinity for 5-HT<sub>2A</sub> receptors has any clinical implications.

## Histamine H<sub>1</sub> Receptors

Cariprazine's moderate affinity for H<sub>1</sub> receptors is roughly equivalent to the affinity of aripiprazole and brexpiprazole for these receptors. Sedation and orthostatic hypotension with high dosages of cariprazine might be related to this property.

## Positron Emission Tomography Studies

Although several marketed antipsychotics have shown moderate in vitro affinity for the D<sub>3</sub> receptor, positron emission tomography (PET) studies have suggested that these compounds do not demonstrate D<sub>3</sub> receptor occupancy in vivo at therapeutic dosages ([Girgis et al. 2016](#)).

Three PET studies have demonstrated cariprazine's excellent brain penetration, showing high and dose-dependent in vivo occupancy of both

dopamine D<sub>3</sub> and D<sub>2</sub> receptors in rodents ([Gyertyán et al. 2011](#)), in monkeys ([Seneca et al. 2011](#)), and in patients with schizophrenia ([Girgis et al. 2016](#)).

In a Phase I open-label three-cohort study, patients with schizophrenia ( $n=3$ ) received multiple-dose cariprazine treatment for 15 days. Cariprazine treatment resulted in high D<sub>2</sub> and D<sub>3</sub> receptor occupancy at all dosages (range, 0.5–12.0 mg/day) and conditions (i.e., acute [day 1], day 4/5, and subchronic [day 15]). A clear dose-occupancy relationship existed for acute, day 4/5, and subchronic treatment, with the highest occupancy for both D<sub>2</sub> and D<sub>3</sub> receptors observed with the highest dosage (12 mg/day).

For dosages of 12 mg/day, 3 mg/day, and 1 mg/day, respectively, the mean D<sub>3</sub> receptor occupancies were 99%, 92%, and 76%, and the mean D<sub>2</sub> receptor occupancies were 95%, 79%, and 45%.

For acute (day 1/4) dosing, the median effective dose (ED<sub>50</sub>) was 1.52 mg for D<sub>3</sub> receptor occupancy and 1.84 mg for D<sub>2</sub> occupancy, with a D<sub>3</sub>/D<sub>2</sub> selectivity ratio range of 1.21–1.31. For subchronic [day 15] dosing, the ED<sub>50</sub> was 0.30 mg for D<sub>3</sub> receptor occupancy and 1.03 mg for D<sub>2</sub> occupancy, with a D<sub>3</sub>/D<sub>2</sub> selectivity ratio range of 3.43–5.75.

Cariprazine showed high and dose-dependent in vivo occupancy of both dopamine D<sub>3</sub> and D<sub>2</sub> receptors in patients with schizophrenia. After subchronic (15-day) administration, cariprazine showed a threefold greater preference for D<sub>3</sub> versus D<sub>2</sub> receptors. The increased D<sub>3</sub>/D<sub>2</sub> selectivity after subchronic dosing compared with acute dosing may be related to the pharmacological activity of cariprazine's metabolites ([Girgis et al. 2016](#)).

---

## Pharmacokinetics

---

In a Phase II double-blind, placebo-controlled tolerance study, the pharmacokinetic properties of cariprazine were similar in healthy volunteers and schizophrenia patients, and there were no significant clinical changes in pharmacokinetic properties by age, sex, or race/ethnicity ([Kapás et al. 2008](#)).

In premarketing studies investigating cariprazine's tolerability in specific populations, patients with either mild or moderate hepatic impairment (Child-Pugh score between 5 and 9), in comparison with healthy subjects, had approximately 25% higher exposure (peak serum concentration [ $C_{\max}$ ] and AUC [area under the concentration curve]) to the parent drug, and approximately 45% lower exposure to the major active metabolites (DCAR and DDCA), following a single daily dose of 1 mg cariprazine or 0.5 mg cariprazine for 14 days). Pharmacokinetic analyses in patients with renal

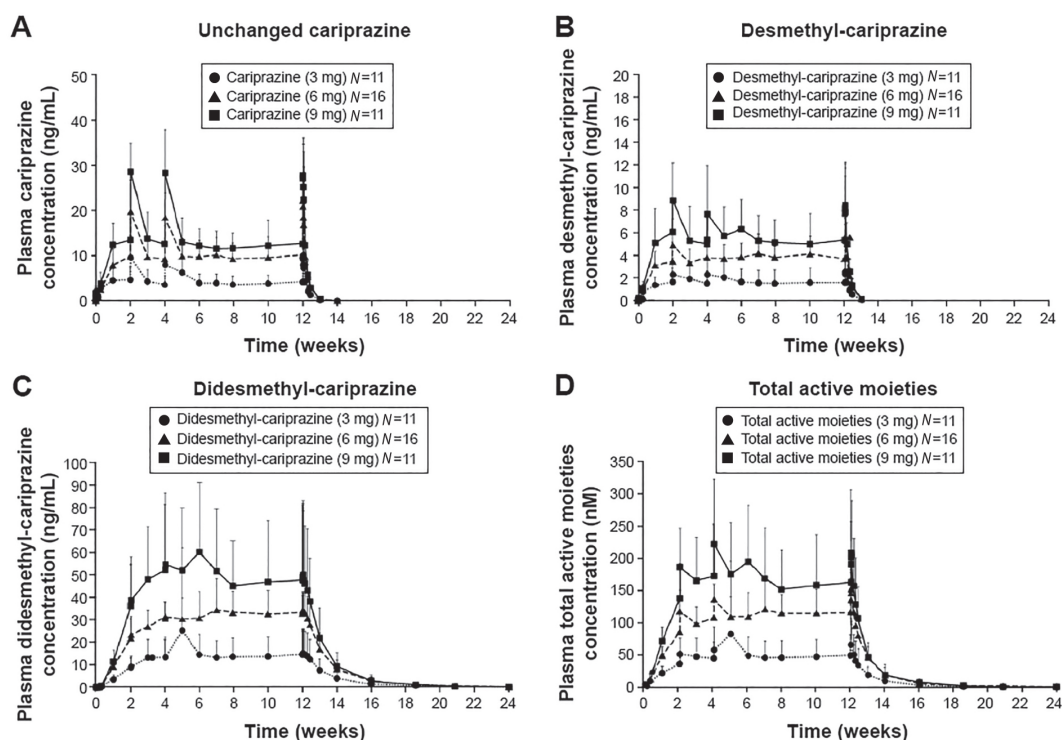

impairment showed no significant relationship between plasma clearance and creatinine clearance ([Actavis Inc. 2015](#)).

## Absorption and Distribution

Cariprazine can be taken with or without food. Food causes a slight delay but has no significant effect on the extent of absorption ([Citrome 2013a](#)).

The effect of a meal on the pharmacokinetics of cariprazine was evaluated in an open-label randomized crossover study in 12 healthy male volunteers who received a single oral dose of 2 mg.  $T_{max}$  was observed at 3–4 hours under fasting conditions. Previous consumption of a meal delayed absorption of the drug but did not affect the final extent of absorption. The plasma profile of cariprazine followed a multi-exponential disposition, with a terminal half-life of 5–6 days ([Veselinovic et al. 2013](#)).

Peak serum concentrations are reached between 3 and 6 hours. There is a linear relationship between dose and plasma concentration. Cariprazine and its major active metabolites are highly bound (91%–97%) to plasma proteins ([Actavis Inc. 2015](#)). Cariprazine and DCAR reach steady-state concentrations within 1–2 weeks ([Figure 34-3](#)); by contrast, DDCAR requires 4–8 weeks of daily cariprazine administration to reach steady-state levels.

---

**FIGURE 34-3.** Plasma concentrations of cariprazine **(A)**, desmethyl-cariprazine **(B)**, didesmethyl-cariprazine **(C)**, and total active moieties (sum of cariprazine, desmethyl-cariprazine and didesmethyl-cariprazine) **(D)** for each dosage group during the treatment and follow-up periods.

*Note.* Data are mean  $\pm$  standard deviation. The lower limit of quantification of analytes was 0.02 ng/mL. The mean was not plotted when at least half of the results were below the lower limit of detection except at time=0.

*Source.* Reprinted from Nakamura T, Kubota T, Iwakaji A, et al.: "Clinical Pharmacology Study of Cariprazine (MP-214) in Patients With Schizophrenia (12-Week Treatment)." *Drug Design, Development and Therapy* 10:327-338, 2016. Copyright © 2016, Dove Medical Press Ltd. Used with permission.

Effective half-life (calculated from time to steady state) of total active moieties was  $\pm 1$  week. Terminal half-lives of cariprazine, DCAR, and DDCAR range from 31.6 to 68.4, 29.7 to 37.5, and 314 to 446 hours, respectively ([Nakamura et al. 2016](#)).

The mean half-life of cariprazine is 2-5 days over a dosage range of 1.5-12.5 mg/day, which is considerably longer (days) than the mean half-life in laboratory animal studies (hours in rats and dogs) ([Mészáros et al. 2008](#)).

On the first day of dosing, systemic exposure to the metabolites (DCAR and DDCAR) was relatively low compared with exposure to the parent drug. However, on day 37, with the 12.5-mg/day dosage, systemic exposure to DDCAR was threefold greater than that to cariprazine for the AUC over 24 hours and sixfold greater for the AUC over 7 days, indicating a slower elimination and a substantially longer half-life for this metabolite than for the parent compound ([Veselinovic et al. 2013](#)).

After initiating cariprazine therapy or changing the dosage, response and side effects should be monitored for several weeks because of the long half-life of cariprazine's active metabolite DDCAR.

## Metabolism and Elimination

Cariprazine is extensively metabolized by hydroxylation and demethylation in the liver cytochrome P450 (CYP) enzyme system, mainly by the 3A4 enzyme and to a lesser extent by the 2D6 enzyme. Eight metabolites for cariprazine were identified in liver microsomes, but only two active metabolites, DCAR and DDCAR, were clinically relevant (equipotent to cariprazine with similar receptor partial agonism) ([Veselinovic et al. 2013](#)).

Cariprazine's main metabolite, DCAR, is further metabolized by CYP3A4 and CYP2D6 to DDCAR, which is metabolized by CYP3A4 to a hydroxylated

metabolite ([Actavis Inc. 2015](#)).

Cariprazine and DCAR levels had decreased by more than 90% at 1 week after the last dose, whereas DDCAR levels had decreased by approximately 50% at 1 week; total active moieties had decreased by approximately 90% at 4 weeks. Cariprazine and its metabolites were eliminated almost completely in the 12 weeks following the last cariprazine dose ([Nakamura et al. 2016](#)).

Following administration of cariprazine 12.5 mg/day to patients with schizophrenia for 27 days, about 21% of the daily dosage was found in urine, with approximately 1.2% of the daily dosage excreted in urine as unchanged cariprazine ([Actavis Inc. 2015](#)).

## Drug–Drug Interactions

Cariprazine and its major active metabolites are weak competitive inhibitors of the human CYP2D6 and CYP3A4 isozymes. They have no induction effect on the CYP enzyme system in human hepatocytes. Cariprazine is a weak inhibitor of a number of CYP450 isoenzymes in vitro: 1A2, 2C9, 2D6, 3A4, 2C19, 2A6, and 2E1.

Because cariprazine is highly metabolized by CYP3A4 and to some degree by CYP2D6, changes in steady-state plasma concentrations would be expected if the drug were coadministered with potent CYP3A4 inhibitors or inducers. However, CYP2D6 inducers or inhibitors are not expected to have this effect on cariprazine metabolism, because CYP2D6 is known to be a poor metabolizer of cariprazine and its metabolites.

Taking a strong CYP3A4 inhibitor (e.g., ketoconazole, fluoxetine, grapefruit juice) with cariprazine will increase concentrations of the parent drug by about 3.5-fold, decrease DCAR by about one-third, and increase DDCAR by about 1.5-fold. The concomitant use of CYP3A4 inducers with cariprazine has not yet been evaluated. When cariprazine is to be added to an existing regimen of a strong CYP3A4 inhibitor, the recommended starting dosage is 1.5 mg every other day, with a maximum dosage of 3 mg/day ([Actavis Inc. 2015](#)).

The absence of any significant effect on the CYP system permits cariprazine to be used in combination with other psychotropics if needed clinically without significant drug–drug interactions. No such combination studies have been published to date.

---

## Indications, Dosing, and Efficacy

---

Cariprazine has a half-life greater than 24 hours, which allows once-daily dosing, an advantage in terms of antipsychotic adherence. Cariprazine has a relatively broad therapeutic index, in that dosages in the range of 0.5–12.5 mg/day are well tolerated. The minimum cariprazine starting dosage is 1.5 mg/day. The minimum therapeutic dosage for schizophrenia is 1.5 mg/day, and that for bipolar disorder is 3 mg/day; however, the maximum recommended target dosage is 6 mg/day for both illnesses. Any dosage changes will be reflected fully in the serum level 2 weeks after initial dosing. In short-term controlled trials, dosages above 6 mg/day did not confer increased effectiveness sufficient to outweigh dose-related adverse reactions. The use of cariprazine in geriatric or pediatric patients has not been studied ([Actavis Inc. 2015](#)).

## FDA-Approved Indications

### Schizophrenia

In the treatment of patients with schizophrenia, the recommended dosage of cariprazine is 1.5–6 mg/day. The recommended starting dosage is 1.5 mg/day, which can be increased to 3 mg/day on day 2, with further upward dosage increments of 1.5 or 3 mg/day as necessary, depending on clinical response and tolerability.

FDA approval for the schizophrenia was based on data from three positive 6-week double-blind, randomized controlled studies of cariprazine that were conducted in adult patients with schizophrenia between 2008 and 2011. Two of the studies used fixed dosages and included active drug comparators (risperidone and aripiprazole) and placebo. All three trials consisted of a washout period of up to 1 week, 6 weeks of double-blind treatment, and a 2-week safety follow-up. The primary efficacy measure in each study was change from baseline in Positive and Negative Syndrome Scale (PANSS) Total score; assessments were conducted at screening, at baseline, and at the end of each double-blind treatment week (weeks 1–6) ([Table 34–2](#)).

**TABLE 34–2. Three 6-week randomized, placebo-controlled trials establishing the efficacy of cariprazine in treating acute schizophrenia**

Trial <sup>a</sup>	Randomization (N)	Efficacy <sup>b</sup>	Side effects
--------------------	----------------------	-----------------------	--------------

<b>Trial<sup>a</sup></b>	<b>Randomization (N)</b>	<b>Efficacy<sup>b</sup></b>	<b>Side effects</b>
NCT00694707 RGH-MD-16 Phase II (Durgam et al. 2014)	Total N: 732 64% completed the study Placebo (151) Cariprazine fixed dosages: 1.5 mg/day (145) 3 mg/day (147) 4.5 mg/day (148) Active control: Risperidone 4 mg/day (141) <sup>c</sup>	At week 6, statistically significant ( $P<0.001$ [LOCF]) LSMD in favor of cariprazine versus placebo were observed for <ul style="list-style-type: none"> <li>PANSS-Total (1.5 mg/day: −7.6; 3 mg/day: −8.8; 4.5 mg/day: −10.4)</li> <li>CGI-S (1.5 mg/day: −0.4; 3 mg/day: −0.5; 4.5 mg/day: −0.6)</li> </ul> Risperidone was superior to placebo on both measures (LSMD: PANSS=−15.1, $P<0.001$ [LOCF]; CGI-S=−0.8, $P<0.05$ [LOCF]).	The most frequent cariprazine adverse events (≥5% and twice the rate of placebo) were akathisia, extrapyramidal disorder, insomnia, sedation, nausea, dizziness, and constipation. Mean changes in metabolic parameters were small and similar between groups.

<b>Trial<sup>a</sup></b>	<b>Randomization (N)</b>	<b>Efficacy<sup>b</sup></b>	<b>Side effects</b>
NCT01104766 RGH-MD-04 Phase III ( <a href="#">Laszlovszky et al. 2014</a> )	Total N: 617 Placebo (153) Cariprazine fixed dosages: 3 mg/day (155) 6 mg/day (157) Active control: Aripiprazole 10 mg/day (152) <sup>c</sup>	At week 6, statistically significant LSMD in favor of cariprazine versus placebo were observed for <ul style="list-style-type: none"> <li>• PANSS-Total (3 mg/day: -6.0, <math>P=0.0044</math>; 6 mg/day: -8.8, <math>P&lt;0.0001</math>)</li> <li>• CGI-S (3 mg/day: -0.4, <math>P=0.0044</math>; 6 mg/day: -0.5, <math>P&lt;0.0001</math>)</li> </ul> Aripiprazole was superior to placebo on both measures (LSMD: PANSS- Total=-7.0, $P=0.0008$ ; CGI- S=-0.4, $P=0.0001$ ).	Akathisia was reported ( $\geq 5\%$ ; twice the rate of placebo). Changes in metabolic parameters were small and similar to those with placebo.

<b>Trial<sup>a</sup></b>	<b>Randomization (N)</b>	<b>Efficacy<sup>b</sup></b>	<b>Side effects</b>
NCT01104779 RGH-MD-05 Phase III (Kane et al. 2015)	Total N: 446 60.5% completed the study Placebo (147) Cariprazine flexible dosing: 3-6 mg/day (151) 6-9 mg/day (148) No active control group	At week 6, statistically significant LSMD in favor of cariprazine versus placebo were observed for <ul style="list-style-type: none"> <li>• PANSS-Total (3-6 mg/day: -6.8, <math>P=0.003</math>; 6-9 mg/day: -9.9, <math>P&lt;0.001</math>)</li> <li>• CGI-S (3-6 mg/day: -0.3, <math>P=0.012</math>; 6-9 mg/day: -0.5, <math>P&lt;0.001</math>)</li> </ul>	The most frequent cariprazine adverse events ( $\geq 5\%$ ; twice the rate of placebo) in both cariprazine groups were akathisia, extrapyramidal disorder, and tremor; most were mild to moderate in severity. Mean changes in metabolic parameters were generally small and similar between groups. Prolactin levels decreased in all groups.

*Note.* CGI-S=Clinical Global Impression-Severity; LOCF=last observation carried forward; LSMD=least squares mean differences; PANSS=Positive and Negative Syndrome Scale.

<sup>a</sup>Trial registration: [ClinicalTrials.gov](https://clinicaltrials.gov) identifiers NCT00694707, NCT01104766, and NCT01104779.

<sup>b</sup>In each study, the PANSS was used as the primary measure and the CGI-S rating scale was used as the secondary efficacy measure. The primary endpoint was change from baseline in PANSS total score at the end of week 6. The change from baseline for cariprazine and for all active control groups was superior to placebo in all three trials.

<sup>c</sup>The active control medications (aripiprazole and risperidone) were included for use in assessment of assay sensitivity and not for efficacy comparisons. However, they were superior to placebo.

As indicated in [Table 34-2](#), patients were randomly assigned to receive cariprazine (1.5 mg/day, 3 mg/day, or 4.5 mg/day); risperidone (4 mg/day); or placebo in the NCT00694707 study; cariprazine (3 mg/day or 6 mg/day), aripiprazole (10 mg/day), or placebo in the NCT01104766 study; and cariprazine (3–6 mg/day or 6–9 mg/day) or placebo in the NCT01104779 study. The efficacy of cariprazine compared with placebo was demonstrated at dosages ranging from 1.5 to 9 mg/day. There was, however, a dose-related increase in certain adverse effects (e.g., EPS), particularly at dosages above 6 mg/day. Findings on the time course of efficacy in the NCT01104766 study are shown in [Figure 34-4](#).

**FIGURE 34-4.** Change from baseline in Positive and Negative Syndrome Scale (PANSS) Total score, by weekly visit (Study ID: NCT01104766).

Source. [Actavis Inc. 2015](#).

In Phase III clinical trials, dosages of 3–9 mg/day produced significant improvement on the PANSS and on the Clinical Global Impression scale. Higher dosages (6–9 mg/day) showed early separation from placebo (by the end of week 1) but carried a dosage-related risk of adverse events, leading the FDA to recommend 6 mg/day as the maximum dosage ([Mattingly and Anderson 2016](#)).

The effects of cariprazine on human cognition were evaluated in the NCT 01104779 study (weeks 0, 3, and 6). No significant differences were

observed for the cariprazine group versus the placebo group on the Cognitive Drug Research System Attention Battery Tests or the Color Trails Test ([Kane et al. 2015](#)).

Data on direct comparisons of clinical efficacy between cariprazine and aripiprazole or risperidone are not yet available ([Veselinovic et al. 2013](#)).

A recent 6-week double-blind, placebo-controlled proof-of-concept study (NCT00404573) evaluated the efficacy, safety, and tolerability of low-dosage (1.5–4.5 mg/day) versus high-dosage (6–12 mg/day) cariprazine in patients with schizophrenia. Surprisingly, no significant differences between the two dosages of cariprazine and placebo were noted on PANSS Total score changes or any other efficacy parameters (Clinical Global Impression–Severity [CGI-S] scale or PANSS subscales) after multiplicity adjustment ([Durgam et al. 2016b](#)).

### Acute Manic or Mixed Episodes Associated With Bipolar I Disorder

Cariprazine’s efficacy in the treatment of bipolar manic or mixed episodes was established at dosages ranging from 3 to 12 mg/day. Dosages above 6 mg/day did not appear to add additional benefit over lower dosages, and there was a dose-related increase in certain adverse effects (e.g., EPS). Therefore, the maximum recommended dosage is 6 mg/day. Findings on the time course of efficacy in the NCT01058668 study are shown in [Figure 34-5](#) ([Vraylar 2015](#)).

**FIGURE 34-5.** Change from baseline in Young Mania Rating Scale (YMRS) Total score, by study visit (Study ID: NCT01058668).

Source. Actavis Inc. 2015.

FDA approval for the bipolar disorder indication was based on data from three 3-week placebo-controlled trials in adults with manic or mixed episodes of bipolar I disorder with or without psychotic features. All three studies demonstrated cariprazine's superiority over placebo (Table 34-3).

**TABLE 34-3. Three 3-week randomized, placebo-controlled, flexibly dosed trials establishing the efficacy of cariprazine in acute manic/mixed episodes of bipolar I disorder**

<b>Trial<sup>a</sup></b>	<b>Randomization (N)</b>	<b>Efficacy<sup>b</sup></b>	<b>Side effects</b>
NCT01058668 Phase III (Calabrese et al. 2015)	Total N: 497 74% completed the study Cariprazine flexible dosing: 3-6 mg/day (169) 6-9 mg/day (167) Placebo (161)	At week 3, statistically significant LSMD in favor of cariprazine versus placebo were observed for <ul style="list-style-type: none"> <li>• YMRS-Total (3-6 mg/day, -6.1; 6-12 mg/day, -5.9; <math>P &lt; 0.001</math> [both])</li> <li>• CGI-S (3-6 mg/day, -0.6; 6-12 mg/day, -0.6; <math>P &lt; 0.001</math> [both])</li> </ul>	The most common ( $\geq 5\%$ ; twice the rate of placebo) treatment-related adverse events for cariprazine were akathisia (both groups) and nausea, constipation, and tremor (6-12 mg/day only).

<b>Trial<sup>a</sup></b>	<b>Randomization (N)</b>	<b>Efficacy<sup>b</sup></b>	<b>Side effects</b>
NCT00488618 Phase II ( <a href="#">Durgam et al. 2015</a> )	Total N: (235) 61.9% of placebo group and 63.6% of cariprazine group completed the study Cariprazine flexible dosing: 3-12 mg/day (118) Placebo (117)	At week 3, statistically significant LSMD in favor of cariprazine versus placebo were observed for <ul style="list-style-type: none"> <li>• YMRS-Total (3-12 mg/day, -6.1; <math>P&lt;0.001</math>)</li> <li>• CGI-S (3-12 mg/day, -0.6; <math>P&lt;0.001</math>)</li> </ul>	The most common adverse events (>10% for cariprazine) were akathisia (cariprazine: 22%; placebo: 6%), extrapyramidal symptoms (parkinsonism) (cariprazine: 16%; placebo: 1%), headache, constipation, nausea, and dyspepsia.  Changes in metabolic parameters were similar between groups, with the exception of fasting glucose change.

<b>Trial<sup>a</sup></b>	<b>Randomization (N)</b>	<b>Efficacy<sup>b</sup></b>	<b>Side effects</b>
NCT01058096 Phase III ( <a href="#">Sachs et al. 2015</a> )	Total N: 310 68.4% completed the study Cariprazine flexible dosing: 3-12 mg/day (158) Placebo (152)	At week 3, statistically significant LSMD in favor of cariprazine versus placebo were observed for <ul style="list-style-type: none"> <li>• YMRS-Total (3-12 mg/day, -4.3; <math>P=0.0004</math>)</li> <li>• CGI-S (3-12 mg/day, -0.4; <math>P=0.0027</math>)</li> </ul>	The most common cariprazine-related (>10%; twice the rate of placebo) treatment-emergent adverse events were akathisia, extrapyramidal disorder, tremor, dyspepsia, and vomiting. Mean changes from baseline in metabolic parameters were generally small and similar between groups.

*Note.* CGI-S=Clinical Global Impression-Severity; LSMD=least squares mean differences; YMRS-Total=Young Mania Rating Scale total score.

<sup>a</sup>Trial registration: [ClinicalTrials.gov](#) identifiers NCT01058668, NCT00488618, and NCT01058096.

<sup>b</sup>In all trials, patients were adults (ages 18-65 years; mean age=39 years) whose symptoms met DSM-IV-TR criteria for bipolar I disorder with manic or mixed episodes and with or without psychotic features (YMRS score $\geq$ 20). YMRS and CGI-S were used as the primary and secondary efficacy measures, respectively; the primary endpoint was decrease from baseline in YMRS-Total score at the end of week 3. The change from baseline for cariprazine was superior to placebo in all three trials. All three trials lacked an active comparator arm and had a short duration.

As indicated in [Table 34-3](#), patients were randomly assigned to receive flexible dosages (3-12 mg/day) of cariprazine or placebo. No active comparator arm was included.

# Possible Future Indications

## Bipolar Depression

Two studies failed to establish cariprazine's efficacy in patients with bipolar depression. In a Phase II ( $N=233$ ) 8-week randomized, double-blind, parallel-group, flexible-dose multicenter trial of cariprazine (0.25–0.75 mg/day or 1.5–3.0 mg/day) in bipolar depression, improvement with cariprazine versus placebo did not reach significance on the primary efficacy measure (change from baseline to week 8 on the Montgomery-Åsberg Depression Rating Scale (MADRS) using mixed model repeated measures [MMRM] analyses). The authors speculated that high placebo response may have contributed to the outcome ([Ahuja et al. 2011](#)).

In a recent 8-week multinational randomized, double-blind, placebo-controlled, parallel-group, fixed-dose (0.75, 1.5, or 3 mg/day) multicenter study of cariprazine in adults ( $N=571$ ) experiencing a current major depressive episode in bipolar I disorder, improvement with cariprazine versus placebo did not reach significance on the primary assessment (MADRS change from baseline to week 6 using MMRM analyses). The 0.75 mg/day dosage did not separate from placebo; however, the 1.5 mg/day dosage produced greater improvement on the MADRS total score change compared with the 3 mg/day dosage ([Durgam et al. 2016a](#)).

## Major Depressive Disorder (Adjunctive Therapy)

A Phase III trial of cariprazine as an adjunct to antidepressant treatment in adult patients with major depressive disorder (NCT01715805) is in progress. In this randomized, double-blind trial, patients will receive oral cariprazine 1.5–4.5 mg/day or placebo for 8 weeks in addition to antidepressant therapy. The primary endpoint is change on the MADRS score at 8 weeks, and the secondary endpoint is change on the Sheehan Disability Scale score at 8 weeks. The trial is recruiting approximately 1,100 patients in the United States and Puerto Rico ([McCormack 2015](#)).

Another Phase III extension trial to assess the long-term safety and tolerability of cariprazine as an adjunct to antidepressant therapy in adult patients with major depressive disorder (NCT01838876) is under way. This 26-week open-label, flexible-dose (1.5–4.5 mg/day) study has enrolled 347 patients, and the final data collection point was scheduled for July 2015 ([McCormack 2015](#)).

## Substance Use Disorders

Cariprazine is being investigated for its potential anti-abuse/relapse-preventing effects in preclinical studies. In a study by [Román et al. \(2013\)](#),

cariprazine, as well as aripiprazole and bifeprunox, reduced the rewarding effects of cocaine (minimum effective doses were 0.17, 1.0, and 0.1 mg/kg for cariprazine, aripiprazole, and bifeprunox, respectively) and delayed relapse to cocaine seeking, with ED<sub>50</sub> values of 0.2, 4.2, and 0.17 mg/kg, respectively. The behavioral effects of cariprazine were as potent as those of bifeprunox and were more potent than those of aripiprazole ([Román et al. 2013](#)).

## Hostility

Using pooled data from the three positive randomized controlled trials in schizophrenia conducted between 2008 and 2011, a post hoc analysis was performed to investigate the effect of cariprazine on hostility in patients with schizophrenia ([Citrome et al. 2016](#)).

Statistically significant improvement (as assessed by mean change from baseline to week 6 on the PANSS Hostility item) was seen in cariprazine-treated versus placebo-treated patients. Antihostility effects were partially independent of improvement on PANSS Positive symptom items, were independent of sedation effects, and were greater in cariprazine-treated patients with higher versus lower baseline levels of hostility ([Citrome et al. 2016](#)).

---

## Side Effects and Toxicology

---

Cariprazine generally was well tolerated in short-term trials for schizophrenia and bipolar I disorder. No significant anticholinergic or antiadrenergic side effects were documented, because cariprazine has negligible affinity for cholinergic or adrenergic receptors.

## Common Treatment-Emergent Adverse Events in Clinical Trials

### 12-Week Open-Label Study

In a 12-week open-label, fixed-dose (3, 6, or 9 mg/day) study of 38 adult patients with schizophrenia ([Nakamura et al. 2016](#)), the overall completion rate was 63.2%; 15.8% of patients discontinued the medication because of adverse events.

Incidence of treatment-emergent adverse events (TEAEs) was 97.4%. No abnormal laboratory values or major differences from baseline in EPS were

observed. A total of 37 (97.4%) patients reported at least one TEAE, and 31 (81.6%) patients experienced at least one adverse drug reaction (defined as adverse events for which a causal relationship with cariprazine was determined to be “reasonably possible”). Side effects observed in this study were similar to those reported in previous studies. Across all dosage groups, akathisia was observed in 21% of patients during cariprazine treatment. One case of cataract (deemed mild in severity) was reported (Nakamura et al. 2016).

## 48-Week Open-Label Studies

In two 48-week studies ( $N=679$ ) of open-label, flexible-dose cariprazine in adult patients with schizophrenia (NCT01104792, 3–9 mg/day; NCT00839852, 1.5–4.5 mg/day) (reported by Nasrallah et al. 2014), the overall completion rate was 40.1%. The mean duration of treatment with cariprazine (days $\pm$ SD) was 188.4 $\pm$ 136.8; 211 patients (31.1%) were exposed to cariprazine for at least 1 year.

Incidence of TEAEs was 81.4%. TEAEs reported in at least 10% of patients were akathisia (15.5%), insomnia (13.1%), headache (12.7%), and weight gain (10.5%) (Table 34-4). The mean increase in body weight was 2.46 kg. Mean changes from baseline to the end of study in metabolic parameters and other clinical laboratory values, blood pressure, and electrocardiographic parameters were generally small. No patients met criteria for Hy’s law (regarding risk of fatal drug-induced liver injury). Mean prolactin levels decreased from baseline to the end of study. The incidence of treatment-emergent parkinsonism (Simpson-Angus Scale score  $>3$ ) was 10.7%, and the incidence of treatment-emergent akathisia (Barnes Akathisia Rating Scale score  $>2$ ) was 17.8%. Ophthalmological testing revealed no significant changes.

**TABLE 34-4. Most frequent<sup>a</sup> treatment-emergent adverse events (TEAEs) during long-term treatment with cariprazine ( $N=679$ )**

TEAE	<i>n</i> (%)
Akathisia	105 (15.5)

*Source.* Reprinted from Nasrallah HA, Cutler AJ, Wang Y, et al.: "P.3.d.025 Safety and Tolerability of Cariprazine in Long-Term Treatment of Schizophrenia: Integrated Summary of Safety Data" (poster & abstract). *European Neuropsychopharmacology* 24 (Suppl 2):S536, 2014, Table 2. Copyright © 2014, Elsevier. Used with permission.

Serious adverse events were reported in 79 patients (11.6%), including one death (suicide) during the open-label treatment period. The most common serious adverse events were worsening of schizophrenia (4.4%) and psychotic disorder (2.1%) ([Nasrallah et al. 2014](#)).

### **16-Week Open-Label Study**

In a 16-week study ( $N=402$ ) of open-label, flexible-dose cariprazine 3–12 mg/day in adult patients with bipolar mania ([Ketter et al. 2013](#)), the overall completion rate was 33%; 16% of patients discontinued the medication because of adverse events. The mean treatment duration was 57.7 days, and the mean cariprazine dosage was 6.2 mg/day. No deaths were reported.

Incidence of TEAEs was 83%. TEAEs reported in at least 10% of patients were akathisia (33%), headache (17%), constipation (11%), and nausea (10%); overall, EPS-related TEAEs were reported in 46% of patients.

Suicidal ideation and behavior (assessed with the Columbia Suicide Severity Rating Scale) occurred in 9% and 1% of patients, respectively; suicidal ideation and suicide attempt occurred in 4 and 3 patients, respectively. The mean body weight increase was <1 kg; 9% of patients had  $\geq 7\%$  weight gain. Mean changes in laboratory values, vital signs, electrocardiogram results, and ophthalmology parameters were generally small. Cariprazine treatment was not associated with an increase in prolactin levels.

Serious adverse events occurred in 8% of patients; most serious adverse events were associated with worsening of mania, depression, or akathisia. The most common adverse events leading to discontinuation were akathisia (5%) and depression (2%) ([Ketter et al. 2013](#)).

## Atypical Antipsychotic Class Warnings

Cariprazine has not been approved for use in the treatment of pediatric or geriatric patients.

Numerous risks are associated with the use of atypical antipsychotic medications in general. As a member of this class, cariprazine carries the following risks ([Actavis Inc. 2015](#)):

1. Increased mortality in elderly patients with dementia-related psychosis
2. Increased risk of cerebrovascular adverse reactions, including stroke, in elderly patients with dementia-related psychosis
3. Neuroleptic malignant syndrome
4. Tardive dyskinesia
5. Leukopenia, neutropenia, and agranulocytosis
6. Seizures
7. Potential for cognitive and motor impairment
8. Body temperature dysregulation
9. Dysphagia

The boxed warnings are based on the pharmacological actions of this class. No such effects were observed in the cariprazine studies, possibly because of the short lengths of the trials.

## Late-Occurring Adverse Drug Reactions

Cariprazine has a long half-life, but the half-lives of its major metabolites are even longer. Therefore, plasma levels accumulate over time, and side effects may appear weeks after the initiation of treatment. As a result, the incidence of adverse reactions in short-term trials may not reflect the rates after

longer-term exposure. Clinicians are advised to monitor for adverse reactions for several weeks after starting a patient on cariprazine and after any dosage increase. If side effects are noted, dosage reduction or medication discontinuation should be considered.

## Akathisia

Across clinical trials for both FDA-approved disorders, akathisia and parkinsonism were among the more common side effects of cariprazine. Both were usually mild, resulting in relatively few premature discontinuations. Parkinsonism appeared to be somewhat dosage-related, whereas akathisia had no clear relationship to dosage ([Mattingly and Anderson 2016](#)).

## Changes in Metabolic and/or Clinical Laboratory Parameters

In the pooled analysis of safety and tolerability data from the two open-label long-term studies discussed earlier ([Nasrallah et al. 2014](#); see “48-Week Open-Label Studies” subsection), mean changes from baseline in plasma lipid levels during long-term cariprazine treatment were small and not clinically meaningful ([Table 34-5](#)). The mean increase in fasting glucose (4.5 mg/dL) was similar to that observed during the 6-week lead-in studies. Mean change from baseline in weight was 1.6 kg. A potentially clinically significant increase in body weight was seen in 27% of patients; a potentially clinically significant decrease was seen in 11% of patients. Mean prolactin levels decreased during long-term cariprazine treatment (see [Table 34-5](#)). Mean alanine transaminase and aspartate transaminase values increased slightly. Creatine kinase levels increased slightly during open-label treatment; however, the large standard deviation indicates that the data were highly variable ([Nasrallah et al. 2014](#)).

<b>TABLE 34-5. Mean changes in metabolic and clinical laboratory parameters after long-term treatment with cariprazine (N=679)</b>
<b>Mean change (SD)</b>

---

**Mean change (SD)**

In schizophrenia clinical trials that included active control medications, the proportion of patients with potentially significant ( $\geq 7\%$ ) weight gain was greater for aripiprazole and risperidone than for cariprazine ([Durgam et al. 2014](#)).

## High Dosage and Overdose

In clinical trials, the 12.5 mg/day dosage was well tolerated in most cases. Several cases of overdose were reported (Trials RGH-PK-15 and RGH-MD-36), at dosages of up to 48 mg/day in one accidental overdose, but in none of those cases was more than supportive measures required ([Citrome 2013a, 2013b](#)).

## Use During Pregnancy and Lactation

There have been no well-controlled studies of cariprazine in pregnant women, but neonates whose mothers have been exposed to other antipsychotic medications during the third trimester of pregnancy are at risk for extrapyramidal and withdrawal symptoms following delivery.

Administration of cariprazine to rats during the period of organogenesis caused malformations, reduced pup survival, and developmental delays at drug exposures less than the human exposure at the maximum recommended human dosage (MRHD) of 6 mg/day. However, cariprazine was not teratogenic in rabbits at doses up to 4.6 times the MRHD of 6 mg/day. Based on animal data, cariprazine may cause fetal harm. Pregnant women should be advised of the potential risk to the fetus ([Actavis Inc. 2015](#)).

---

## Ongoing Cariprazine Trials

---

Numerous trials of cariprazine are currently ongoing or under way ([McCormack 2015](#)):

- Phase III trial of cariprazine in the treatment of schizophrenia or bipolar disorder in some countries of the European Union, India, Russia, South Africa, Serbia, Colombia, and Ukraine
- Phase III trial of cariprazine in the treatment of schizophrenia with predominant negative symptoms in the Czech Republic, Hungary, Spain, Poland, Croatia, France, Serbia, Romania, Russia, Ukraine, and Bulgaria
- Phase III trial of cariprazine in the prevention of relapse of schizophrenia in India, Romania, Slovakia, the United States, and Ukraine
- Phase II/III trial of cariprazine in the treatment of schizophrenia in Japan, South Korea, and Taiwan
- Phase III trial of cariprazine as an adjunct to antidepressant treatment of major depressive disorder in Puerto Rico and the United States
- Phase II trial of cariprazine as an adjunct to antidepressant treatment of major depressive disorder in Estonia, Finland, Slovakia, Sweden, Ukraine, and the United Kingdom
- Phase II trial of cariprazine in the treatment of bipolar depression in Bulgaria, Canada, Colombia, Russia, Ukraine, and the United States

---

## Conclusion

---

Cariprazine combines functional selectivity at dopamine D<sub>3</sub> and D<sub>2</sub> receptors, partial agonist activity at serotonin 5-HT<sub>1A</sub> receptors, and antagonism at serotonin 5-HT<sub>2B</sub> and 5-HT<sub>2A</sub> receptors. Cariprazine's receptor-binding profile is unique, with the highest affinity and selectivity for D<sub>3</sub> receptors of any second-generation antipsychotic. It has antipsychotic and mood-stabilizing effects, as well as possible antidepressant, procognitive, anti-abuse, and antihostility effects. Cariprazine has the potential to improve the cognitive and negative symptoms of schizophrenia, as shown in preclinical trials.

## CHAPTER 35

# Drugs to Treat Extrapyrarnidal Side Effects

Joseph K. Stanilla, M.D.  
George M. Simpson, M.D.

---

## Extrapyrarnidal Side Effects

---

### History

The discovery of the therapeutic properties of chlorpromazine (Delay and Deniker 1952; Laborit et al. 1952) was soon followed by the description of its tendency to produce extrapyramidal side effects (EPS) that were indistinguishable from the symptoms of classic Parkinson's disease. A debate soon arose regarding the relationship between EPS and therapeutic efficacy, with some investigators suggesting that EPS were necessary for efficacy (Flügel 1953; Haase 1954).

Brooks (1956), on the other hand, suggested that "signs of parkinsonism heralded the particular effect being sought" (p. 1122) but that "the therapeutic effects were not dependent on extrapyramidal dysfunction. On the contrary, alleviation of such dysfunction, as soon as it occurred, sped the progress of recovery" (p. 1122).

### Types

Four types of EPS have been delineated, and the treatment of each type should be individualized. *Acute dystonic reactions* (ADRs) are generally the first EPS to appear and are often the most dramatic (Angus and Simpson 1970b). *Dystonias* are involuntary sustained or spasmodic muscle contractions that cause abnormal twisting or rhythmical movements and/or postures. ADRs tend to occur suddenly and generally involve muscles of the head and neck (as in torticollis, facial grimacing, or oculogyric crisis). Nearly 90% of all ADRs occur within 4 days of antipsychotic initiation or dosage increase, and virtually 100% of all ADRs occur by day 10 (Singh et al. 1990; Sramek et al. 1986). Although tardive dystonia can occur after this

period, movements occurring beyond this time frame are much less likely to be ADRs. Instead, other conditions, including seizures, need to be considered.

*Akathisia* is the second type of EPS to appear. Akathisia, meaning “inability to sit,” consists of both an objective restless movement and a subjective feeling of restlessness that the patient experiences as the need to move. It may be difficult for a patient to explain the sensation of akathisia, and the diagnosis can be missed. At times, patients may display the classic movements of akathisia but without the subjective distress, a condition that has been termed *pseudoakathisia*, which may be a type of tardive syndrome ([Barnes 1990](#)).

The third type of EPS, *pseudoparkinsonism*, is virtually indistinguishable from classic Parkinson’s disease. Symptoms of pseudoparkinsonism include a generalized slowing of movement (akinesia), masked facies, rigidity (including cogwheeling rigidity), resting tremor, and hypersalivation. Parkinson-like symptoms generally appear after a few weeks or more of antipsychotic treatment. Akinesia needs to be differentiated from both primary depression and the blunted affect of schizophrenia ([Rifkin et al. 1975](#)).

*Tardive syndromes* make up the fourth group of EPS. Tardive dyskinesia (TD), although clearly associated with the use of antipsychotic medications, was actually described prior to the advent of antipsychotics ([Simpson 2000](#)). TD consists of irregular stereotypical movements of the mouth, face, and tongue and choreoathetoid movements of the fingers, arms, legs, and trunk. It tends to appear after months to years of use of antipsychotic medications. Patients frequently have no awareness of the abnormal movements. The lack of awareness may be related to frontal lobe dysfunction ([Sandyk et al. 1993](#)).

Tardive dystonia, a variant of TD, also generally emerges months to years after treatment with antipsychotics ([Burke et al. 1982](#)). Unlike in ADRs, the movements associated with tardive dystonia tend to be persistent and more resistant to medical treatment ([Kang et al. 1988](#)).

---

## Agents Used to Treat Extrapyramidal Side Effects

---

### Antiparkinsonian Agents for Neuroleptic-Induced Parkinsonism and Acute Dystonic Reactions

Antiparkinsonian medications primarily have been used to treat EPS and include anticholinergic, antihistaminic, and dopaminergic agents ([Table 35-1](#)).

---

**TABLE 35-1. Pharmacological agents for the treatment of neuroleptic-induced parkinsonism and acute dystonic reactions**

---

Compound	Relative equivalence (mg) <sup>a</sup>	Route	Availability	Dosing	Dosage range (mg/day)
Anticholinergics					
Trihexyphenidyl (Artane)	2	Oral	Tablets: 2, 5 mg Elixir: 2 mg/mL	qd-bid	2-30
Benztropine (Cogentin)	1	Oral	Tablets: 0.5, 1, 2 mg	qd-bid	1-12
		Injectable	Ampules: 1 mg/mL (2 mL)	Every 30 minutes (until symptom relief)	2-8
Biperiden (Akineton) <sup>b</sup>	2	Oral	Tablets: 2 mg	qd-bid	2-24
		Injectable	Ampules: 5 mg/mL (1 mL) <sup>b</sup>	Every 30 minutes (until symptom relief)	2-8
Procyclidine (Kemadrin)	2	Oral	Tablets: 5 mg (scored)	bid-tid	5-20
Antihistaminics					
Diphenhydramine (Benadryl)	50	Oral	Tablets: 25, 50 mg	bid-qd	50-200
		Injectable	Ampules: 50 mg/mL (1 mL, 10 mL)		
			Syringe (prefilled): 1 mL		
Dopaminergics					
Amantadine (Symmetrel)	N/A	Oral	Tablets: 100 mg Syrup: 50 mg/5 mL	qd-bid	100-300

*Note.* bid=twice daily; N/A=not applicable; qd=once daily; tid=three times daily.

<sup>a</sup>Adapted from [Klett and Caffey 1972](#).

<sup>b</sup>No longer available as an injectable in the United States.

## Anticholinergic Medications

### Trihexyphenidyl.

*History and discovery.* Trihexyphenidyl, a synthetic analog of atropine, was introduced as benzhexol hydrochloride in 1949. It was found to be effective in the treatment of Parkinson's disease in a study of 411 patients ([Doshay et al. 1954](#)). Thereafter, it was also used to treat neuroleptic-induced parkinsonism (NIP) ([Rashkis and Smarr 1957](#)). (The term *neuroleptic*, derived from Greek and meaning "to clasp the neuron," was introduced to describe chlorpromazine and the extrapyramidal effects that it produced [[Delay et al. 1952](#)].)

*Structure-activity relations.* Trihexyphenidyl, a tertiary-amine analog of atropine, is a competitive antagonist of acetylcholine and other muscarinic agonists that compete for a common binding site on muscarinic receptors ([Yamamura and Snyder 1974](#)). It exerts little blockade at nicotinic receptors ([Timberlake et al. 1961](#)). Trihexyphenidyl and all drugs in this class are referred to as anticholinergic, antimuscarinic, or atropine-like drugs. As a tertiary amine, trihexyphenidyl readily crosses the blood-brain barrier ([Brown and Taylor 1996](#)).

*Pharmacological profile.* The pharmacological properties of trihexyphenidyl are qualitatively similar to those of atropine and other anticholinergic drugs, although trihexyphenidyl acts primarily centrally, with few peripheral effects and little sedation. In the eye, anticholinergic drugs block both the sphincter muscle of the iris, causing the pupil to dilate (mydriasis), and the ciliary muscle of the lens, preventing accommodation and causing cycloplegia. In the heart, anticholinergic drugs usually produce a mild tachycardia through vagal blockade at the sinoatrial node pacemaker, although a mild slowing can occur. In the gastrointestinal tract, anticholinergic drugs reduce gut motility and salivary and gastric secretions. Salivary secretion is particularly sensitive and can be completely abolished. In the respiratory system, anticholinergic agents reduce secretions and can produce mild bronchodilatation. Anticholinergics inhibit the activity of sweat glands and mildly decrease contractions in the urinary and biliary tracts ([Brown and Taylor 1996](#)).

*Pharmacokinetics and disposition.* Peak concentration for trihexyphenidyl is reached 1-2 hours after oral administration, and its half-life is 10-12 hours ([Cedarbaum and McDowell 1987](#)). As a tertiary amine, trihexyphenidyl crosses the blood-brain barrier to enter the central nervous system (CNS).

*Mechanism of action.* The presumed mechanism of action of trihexyphenidyl for treatment of EPS is the blockade of intrastriatal cholinergic activity, which is relatively increased, compared with nigrostriatal dopaminergic activity, which has become decreased by antipsychotic blockade. The blockade of cholinergic activity returns the system to its previous equilibrium.

*Indications.* Anticholinergic agents were reported to have been effective treatment for NIP from open empirical trials ([Medina et al. 1962](#); [Rashkis and Smarr 1957](#)).

Eventually, controlled trials were conducted, with most involving comparisons only with different anticholinergics and not with placebo. Despite the limited evidence of efficacy against placebo, anticholinergic agents became the mainstay of treatment for NIP, and they remain so today.

Trihexyphenidyl has U.S. Food and Drug Administration (FDA) approval for treatment of all forms of parkinsonism, including NIP. Daily dosages of 5–30 mg have been used in studies of trihexyphenidyl in the treatment of Parkinson's disease and NIP. Much higher dosages (up to 75 mg/day) have been used for the treatment of primary dystonia. However, the benefits of high dosages have been limited by the adverse effects on cognition and memory ([Jabbari et al. 1989](#); [Taylor et al. 1991](#)). Side effects correlate with blood levels, but efficacy does not ([Burke and Fahn 1985](#)). The individual therapeutic dosage must be determined empirically and can vary widely.

*Side effects and toxicology.* The *peripheral* side effects of trihexyphenidyl result from parasympathetic muscarinic blockade, and they occur in a consistent hierarchy among different organs. They are qualitatively similar to the side effects of atropine and other anticholinergic drugs, but they are quantitatively less because of the reduced peripheral activity of trihexyphenidyl ([Brown 1990](#)).

Anticholinergic drugs initially depress salivary and bronchial secretions and sweat production. Reduced salivation leads to dry mouth and contributes to the high incidence of dental caries found among patients with chronic psychiatric problems ([Winer and Bahn 1967](#)). Treatment for this condition is unsatisfactory; relief obtained from chewing sugar-free gum or sucking on hard candy is limited by the need for constant use. Reduced sweating can contribute to heat prostration and heatstroke, particularly in warmer ambient temperatures.

The next physiological effects occur in the eyes and heart. Pupillary dilatation and inhibition of accommodation in the eye lead to photophobia and blurred vision. Attacks of acute glaucoma can occur in susceptible subjects with narrow-angle glaucoma, although this is relatively uncommon. Vagus nerve blockade leads to increased heart rate and is more apparent in patients with high vagal tone (usually younger men).

The next effects are inhibition of urinary bladder function and bowel motility, which can produce urinary retention, constipation, and obstipation. Sufficiently high dosages of anticholinergics will inhibit gastric secretion and motility ([Brown and Taylor 1996](#)).

Memory disturbance is the most common *central* side effect of anticholinergic medications because memory is dependent on the cholinergic system ([Drachman 1977](#)). Patients with underlying brain pathology are more susceptible to memory disturbance ([Fayen et al. 1988](#)). Patients with chronic psychiatric conditions often have a decreased ability to express themselves, making evaluation of memory more difficult; therefore, subtle memory changes can be missed or attributed to the underlying illness. Memory disturbances have been identified in patients with Parkinson's disease treated with anticholinergics ([Yahr and Duvoisin 1968](#)), even in some patients receiving only small dosages ([Stephens 1967](#)). Patients receiving an

antipsychotic and benztropine had significantly increased overall scores on the Wechsler Memory Scale when benztropine was withdrawn (Baker et al. 1983).

Anticholinergic toxicity produces restlessness, irritability, disorientation, hallucinations, and delirium. Elderly patients are at increased risk for both memory loss and toxic delirium, even at very low dosages, because of the natural loss of cholinergic neurons with aging (Perry et al. 1977). Toxic dosages can produce a clinical situation identical to atropine poisoning, manifesting as fixed dilated pupils, flushed face, sinus tachycardia, urinary retention, dry mouth, and fever. This condition can proceed to coma, cardiorespiratory collapse, and death.

*Drug-drug interactions.* There may be increased anticholinergic effects, including side effects, when trihexyphenidyl or any anticholinergic is combined with amantadine. Anticholinergic side effects are also much more likely to occur when drugs with anticholinergic properties are combined.

Some investigators have suggested that anticholinergic medications can affect antipsychotic blood levels. However, a review of this subject suggests that the available data are too limited to reach a definite conclusion on this matter. The best studies indicate that anticholinergic drugs do not affect antipsychotic blood levels or, at most, that they lower these levels only transiently (McEvoy 1983).

Haase and Janssen (1965) reported from open studies that when anticholinergic medications are added to antipsychotic medications given at dosages that reach the neuroleptic threshold, rigidity, hypokinesia, and therapeutic effects disappear, but psychopathology worsens. (Haase [1954] postulated that the neuroleptic dosage that produced minimal subclinical rigidity and hypokinesia [i.e., the “neuroleptic threshold”] was the minimum neuroleptic dosage necessary for therapeutic antipsychotic effect and that it was manifested by micrographic handwriting changes.) Other studies have reported no change or an improvement in scores of psychopathology with the addition of anticholinergics (Hanlon et al. 1966; Simpson et al. 1980).

*Anticholinergic abuse.* Anticholinergic drugs may be abused for their euphoriant and hallucinogenic effects, and they may be combined with street drugs for enhanced effect (Crawshaw and Mullen 1984). Patients with a history of substance abuse are more likely to abuse anticholinergics (Wells et al. 1989). Cases of abuse have been reported with all anticholinergics, but trihexyphenidyl apparently is the anticholinergic most likely to be abused (Macvicar 1977). Theoretically, one anticholinergic should be as effective as another, although an idiosyncratic response is possible. The potential for abuse needs to be considered, particularly in patients with a history of substance abuse.

## **Benztropine.**

*History and discovery.* Benztropine was synthesized by uniting the tropine portion of atropine with the benzhydryl portion of diphenhydramine hydrochloride. Benztropine was found to be effective in the treatment of 302 patients with Parkinson’s disease (Doshay 1956). The best results in the control of rigidity, contracture, and tremor were obtained at dosages of 1–4 mg once daily for older

patients and 2–8 mg once daily for younger ones. Dosages of 15–30 mg once daily caused excessive flaccidity in some patients, who became unable to lift their arms or raise their heads off the bed. Subsequently, benztropine was found to be effective for the treatment of NIP ([Karn and Kasper 1959](#)).

*Structure-activity relations.* Benztropine is a tertiary amine with activity similar to that of trihexyphenidyl. As a tertiary amine, benztropine enters the CNS.

*Pharmacological profile.* Benztropine has the pharmacological properties of an anticholinergic and an antihistaminic; however, it produces less sedation (in experimental animals) than does diphenhydramine.

*Pharmacokinetics and disposition.* Little is known about the pharmacokinetics of benztropine. A correlation between serum anticholinergic levels and the presence of EPS has been documented ([Tune and Coyle 1980](#)). There is little correlation between the total daily dosage of benztropine and the serum anticholinergic level, with the serum activity for a given dosage varying 100-fold between subjects. When treated with higher dosages of anticholinergics, patients with EPS show increased serum anticholinergic activity and decreased EPS. Relatively small increments in the oral dosage of an anticholinergic drug can result in significant nonlinear increases in serum anticholinergic activity levels. Benztropine has a long-acting effect and can be given once or twice a day.

*Mechanism of action, side effects, and drug-drug interactions.* The mechanism of action and the drug interactions for benztropine are similar to those of trihexyphenidyl. The side effects of these two drugs are also similar, but the degree of sedation produced by benztropine may be less ([Doshay 1956](#)). Although not yet confirmed in double-blind studies, this reported difference in sedation might account for the fact that trihexyphenidyl is reportedly the anticholinergic drug more likely to be abused.

*Indications.* Benztropine has FDA approval for the treatment of all forms of parkinsonism, including NIP. Total daily dosages of 1–8 mg generally have been used to treat NIP.

**Biperiden.** Biperiden is an analog of trihexyphenidyl that has greater peripheral anticholinergic activity than trihexyphenidyl and greater activity against nicotinic receptors ([Timberlake et al. 1961](#)). Biperiden is well absorbed from the gastrointestinal tract. Its metabolism, although not completely understood, involves hydroxylation in the liver. Its activity, pharmacological profile, and side effects are similar to those of other anticholinergics. It has FDA approval for use in the treatment of all forms of parkinsonism, including NIP. Total daily dosages of 2–24 mg have been used in studies of biperiden for the treatment of parkinsonism and NIP.

**Procyclidine.** Procyclidine is an analog of trihexyphenidyl ([Schwab and Chafetz 1955](#)). Its activity, pharmacology, and side effects are similar to those of other anticholinergics. There is little information about its pharmacokinetics. Procyclidine has FDA approval for use in treating all forms of parkinsonism, including NIP. Total

daily dosages of 5–30 mg have been used in studies of procyclidine for the treatment of parkinsonism and NIP.

## Antihistaminic Medications

### Diphenhydramine.

*History and discovery.* Antihistaminic agents have been used for the treatment of Parkinson's disease. Diphenhydramine, one of the first antihistamines developed and used clinically (Bovet 1950), has been the primary antihistamine studied in the treatment of EPS. Although some antihistamines may be effective, other antihistamines have not been systematically studied for the treatment of EPS.

*Structure-activity relations.* All drugs referred to as antihistamines are reversible competitive inhibitors of histamine at the histamine-1 ( $H_1$ ) receptor. Some antihistamines also inhibit the action of acetylcholine at the muscarinic receptor. It is believed that central muscarinic blockade, rather than histaminic blockade, is responsible for the therapeutic effect of antihistamines for EPS. Ethanolamine antihistamines (diphenhydramine, dimenhydrinate, and carbinoxamine maleate) have the greatest anticholinergic activity, and ethylenediamine antihistamines have the least anticholinergic activity. Antihistamines such as terfenadine and astemizole have no anticholinergic activity, whereas many of the remaining antihistamines have very mild anticholinergic activity (Babe and Serafin 1996).

*Pharmacological profile.* Antihistamines inhibit the constrictor action of histamine on respiratory smooth muscle. They restrict the vasoconstrictor and vasodilatory effects of histamine on vascular smooth muscle and block histamine-induced capillary permeability. Antihistamines with CNS activity are depressants, producing diminished alertness, slowed reaction times, and somnolence. They can also block motion sickness. Antihistaminic drugs with anticholinergic activity also possess mild antimuscarinic pharmacological properties similar to those of other atropine-like drugs (Babe and Serafin 1996).

*Pharmacokinetics and disposition.* Diphenhydramine is well absorbed from the gastrointestinal tract. Peak concentrations occur 2–3 hours after oral administration. Its therapeutic effects usually last 4–6 hours, and it has a half-life of 3–9 hours. Diphenhydramine is widely distributed throughout the body, and as a tertiary amine, it enters the CNS. Age does not affect its pharmacokinetics. It undergoes demethylations in the liver and is then oxidized to carboxylic acid (Paton and Webster 1985).

*Mechanism of action.* Diphenhydramine possesses some anticholinergic activity, which is believed to be the basis for its effect in diminishing EPS.

*Indications.* Diphenhydramine has FDA approval for treatment of parkinsonism, including NIP, in the elderly and for mild cases of parkinsonism in other age groups. It is probably not as efficacious for treating EPS as are pure anticholinergic drugs,

but it may be better tolerated in patients bothered by anticholinergic side effects, such as geriatric patients. Diphenhydramine also tends to be more sedating than anticholinergics, which can be beneficial for some patients. The dosage generally ranges from 50 to 400 mg/day, given in divided doses.

Diphenhydramine also has indications for multiple other conditions that are unrelated to EPS.

*Side effects and toxicology.* The primary side effect of diphenhydramine is sedation. Although other antihistamines may cause gastrointestinal distress, diphenhydramine has a low incidence of such an effect. Drying of the mouth and respiratory passages can occur. In general, the toxic effects are similar to those of trihexyphenidyl and of other anticholinergics.

*Drug-drug interactions.* Diphenhydramine has no reported interactions with other drugs, but it has an additive depressant effect when used in combination with alcohol or with other CNS depressants.

## Dopaminergic Medications

### Amantadine.

*History and discovery.* Anticholinergic side effects and inadequate treatment response eventually led to the investigation of other agents to treat EPS. Initially, both methylphenidate and intravenous caffeine were investigated as treatments for NIP. Neither agent achieved general use, despite apparent efficacy (Brooks 1956; Freyhan 1959).

Amantadine is an antiviral agent that is effective against A2 (Asian) influenza (Wingfield et al. 1969). It was unexpectedly found to produce symptomatic improvement in patients with Parkinson's disease (Parkes et al. 1970; Schwab et al. 1969), and soon thereafter, it was reported to be effective for NIP (Kelly and Abuzzahab 1971).

*Structure-activity relations.* Amantadine is a water-soluble tricyclic amine. It binds to the M2 protein, a membrane protein that functions as an ion channel on the influenza A virus (Hay 1992). Its activity in reducing EPS is not known, although it has been shown to have activity at glutamate receptors (Stoof et al. 1992).

*Pharmacological profile.* Amantadine is effective in preventing and treating illness from influenza A virus. It also reduces the symptoms of parkinsonism.

*Pharmacokinetics and disposition.* In young healthy subjects, amantadine is slowly and well absorbed from the gastrointestinal tract, with unchanged oral bioavailability over a dosage range of 50–300 mg/day. It reaches steady state in 4–7 days. Plasma concentrations (0.12–1.12 µg/mL) may have some correlation with improvement in EPS (Greenblatt et al. 1977; Pacifici et al. 1976). Amantadine has relatively constant blood levels and a long duration of action (Aoki et al. 1979) and is excreted unchanged by the kidneys. Its half-life for elimination is about 16 hours,

which is prolonged in elderly patients and in patients with impaired renal function ([Hayden et al. 1985](#)).

*Mechanism of action.* Amantadine inhibits viral replication by binding to the M2 protein on the viral membrane and inhibiting replication ([Hay 1992](#)). Its mechanism of action as an antiparkinsonian agent is less clear. It has no anticholinergic activity in tests on animals, being only 1/209,000th as potent as atropine ([Grelak et al. 1970](#)). It appears to cause the release of dopamine and other catecholamines from intraneuronal storage sites via an amphetamine-like mechanism. It has also been shown to have activity at glutamate receptors, which may contribute to its antiparkinsonian effect ([Stoof et al. 1992](#)). Amantadine has preferential selectivity for central catecholamine neurons ([Grelak et al. 1970](#); [Strömberg et al. 1970](#)).

*Indications.* Amantadine has undergone more extensive investigation than have anticholinergic agents with regard to the efficacy for EPS. Most studies, although not all, found amantadine to be equal in efficacy to benztropine or biperiden in the treatment of parkinsonism ([DiMascio et al. 1976](#); [Fann and Lake 1976](#); [König et al. 1996](#); [Silver et al. 1995](#); [Stenson et al. 1976](#)). Some studies found amantadine to be more effective than benztropine ([Merrick and Schmitt 1973](#)) or effective for EPS that are refractory to benztropine ([Gelenberg 1978](#)). However, other studies found that amantadine was inferior to benztropine ([Kelly et al. 1974](#)), no more effective than placebo ([Mindham et al. 1972](#)), or unable to control EPS when used to replace an anticholinergic agent ([McEvoy et al. 1987](#)). The varying results can be attributed to differing methodologies and patient populations.

The conclusion that can be drawn from these studies is that amantadine is an effective drug for treating parkinsonism but that no clear data support its use prior to using anticholinergic agents. Most of the studies were of short duration, and in patients with Parkinson's disease, amantadine appears to lose efficacy after several weeks ([Mawdsley et al. 1972](#); [Schwab et al. 1972](#)). Similar studies evaluating the long-term efficacy of amantadine have not been conducted for EPS.

Amantadine also has been evaluated for the treatment of akathisia, but in only a small number of patients. The conclusion from these studies is that amantadine is probably not effective for treating akathisia ([Fleischhacker et al. 1990](#)).

Amantadine has FDA approval for the treatment of NIP and Parkinson's disease, as well as for the treatment and prophylaxis of influenza A respiratory illness. Dosages of 100–300 mg/day are used for the treatment of NIP, and plasma concentrations may have some correlation with improvement.

*Side effects and toxicology.* At dosages of 100–300 mg/day, amantadine does not produce adverse effects as readily as do anticholinergic medications. Side effects of amantadine result from CNS stimulation, with symptoms including irritability, tremor, dysarthria, ataxia, vertigo, agitation, reduced concentration, hallucinations, and delirium ([Postma and Van Tilburg 1975](#)). Hallucinations are often visual. Side effects are more likely to occur in elderly patients and in patients with reduced renal function ([Borison 1979](#); [Ing et al. 1979](#)). Toxic effects are directly related to elevated amantadine serum levels (>1.5 µg/mL). Resolution of toxic symptoms is dependent

on renal clearance and may require dialysis in extreme cases, although less than 5% of amantadine is removed through dialysis.

Patients with congestive heart failure or peripheral edema should be monitored because of amantadine's ability to increase the availability of catecholamines. Long-term use of amantadine may produce livedo reticularis in the lower extremities from the local release of catecholamines and resulting vasoconstriction ([Cedarbaum and Schleifer 1990](#)). Amantadine should be used with caution in patients with seizures because of possible increased seizure activity. Amantadine is embryotoxic and teratogenic in animals, but there are no well-controlled studies in women regarding teratogenicity.

*Drug-drug interactions.* There are no reported interactions between amantadine and other drugs. There may be increased anticholinergic side effects when amantadine is used in combination with an anticholinergic agent.

## Beta-Adrenergic Receptor Antagonists

**History and discovery.** Propranolol was reported to be effective for the treatment of restless legs syndrome (Ekbom syndrome; [Ekbom 1965](#)), which resembles the physical movements of akathisia ([Strang 1967](#)). Later it was reported to be effective in the treatment of medication-induced akathisia ([Kulik and Wilbur 1983](#); [Lipinski et al. 1983](#)). Subsequently, other  $\beta$ -blockers have been investigated for the treatment of akathisia.

**Structure-activity relations.** Competitive  $\beta$ -adrenergic receptor antagonism is a property common to all  $\beta$ -blockers.  $\beta$ -Blockers are distinguished by the additional properties of their relative affinity for  $\beta_1$  and  $\beta_2$  receptors (selectivity), lipid solubility, intrinsic  $\beta$ -adrenergic receptor *agonist* activity, blockade of receptors, capacity to induce vasodilation, and general pharmacokinetic properties (Hoffman and Lefkowitz [1996](#)).  $\beta$ -Blockers with high lipid solubility readily cross the blood-brain barrier.

**Pharmacological profile.** The major pharmacological effects of  $\beta$ -blockers involve the cardiovascular system.  $\beta$ -Blockers slow the heart rate and decrease cardiac contractility; however, these effects are modest in a normal heart. In the lung, they can cause bronchospasm, although, again, there is little effect in normal lungs. They block glycogenolysis, preventing production of glucose during hypoglycemia ([Hoffman and Lefkowitz 1996](#)).  $\beta$ -Blockers affect lipid metabolism by preventing release of free fatty acids while elevating triglycerides ([Miller 1987](#)). In the CNS, they produce fatigue, sleep disturbance (insomnia and nightmares), and CNS depression (see [Drayer 1987](#); [Gengo et al. 1987](#)).

**Pharmacokinetics and disposition.** All  $\beta$ -blockers, except atenolol and nadolol, are well absorbed from the gastrointestinal tract ([McDevitt 1987](#)). All  $\beta$ -blockers undergo metabolism in the liver. Propranolol and metoprolol undergo significant first-pass effect, with bioavailability as low as 25%. Large interindividual variation (as much as 20-fold) leads to wide variation in clinically therapeutic

dosages (Hoffman and Lefkowitz 1996). Metabolites appear to have limited  $\beta$ -receptor antagonistic activity. The degree to which a particular  $\beta$ -blocker enters the CNS is related directly to its lipid solubility (Table 35-2).

**TABLE 35-2. Characteristics of  $\beta$ -blockers investigated in the treatment of akathisia**

Compound	$\beta_1$ blockade	$\beta_2$ blockade	Lipid solubility	Effective for EPS	Dosage range (mg/day)
Propranolol (Inderal)	++	++	++++	Yes	20-120
Nadolol (Corgard)	++	++	+	Yes	40-80
Metoprolol (Lopressor)	++	0 at low dosages; + at high dosages	++	Yes	~300
Pindolol (Visken)	++	++	++	Yes	5
Atenolol (Tenormin)	++	0	0	No	50-100
Betaxolol (Kerlone)	++	0	+++	Yes	5-20
Sotalol (Betapace, Sorine)	++	++	0	No	40-80

*Note.* EPS=extrapyramidal side effects; 0=insignificant; +=low; ++=moderate; +++=high; ++++=very high.

*Source.* Adapted from Hoffman and Lefkowitz 1996.

**Mechanism of action.** The exact mechanism of action of  $\beta$ -blockers in the treatment of EPS is unclear. The existence of a noradrenergic pathway from the locus coeruleus to the limbic system has been proposed as a modulator involved in symptoms of TD, akathisia, and tremor (Wilbur et al. 1988). It appears that lipid solubility and the corresponding ability to enter the CNS are the most important factors determining the efficacy of a  $\beta$ -blocker in treating akathisia and perhaps other types of EPS (Adler et al. 1991).

**Indications.**  $\beta$ -Blockers have FDA approval primarily for cardiovascular indications, and propranolol is also indicated for familial essential tremor, but there are no FDA-approved indications for the treatment of any type of EPS.

$\beta$ -Blockers have been studied primarily for the treatment of akathisia. Both nonselective ( $\beta_1$  and  $\beta_2$  antagonism) and selective ( $\beta_1$  antagonism)  $\beta$ -blockers have been reported to be efficacious. The studies generally have been for short periods of

time, involving small numbers of patients who were often receiving varying combinations of additional antiparkinsonian agents or benzodiazepines to which  $\beta$ -blockers had been added (Fleischhacker et al. 1990). From these studies, it is difficult to draw any firm conclusions, but  $\beta$ -blockers probably have some efficacy in the treatment of akathisia. The maximum benefit for propranolol occurred at 5 days (Fleischhacker et al. 1990). Betaxolol may be the  $\beta$ -blocker of choice in patients with lung disease and smokers because of its  $\beta_1$  selectivity at lower dosages (5–10 mg/day).

In addition to essential tremor,  $\beta$ -blockers have been reported to be beneficial for the tremor of Parkinson's disease (Foster et al. 1984) and lithium-induced tremor (Gelenberg and Jefferson 1995). However, for neuroleptic-induced tremor, propranolol was found to be not any better than placebo (Metzer et al. 1993), which could be an indication of a difference in etiologies for the different tremors.

**Side effects and toxicology.** The side effects of  $\beta$ -blockers result from  $\beta$ -receptor blockade.  $\beta_2$  blockade of bronchial smooth muscle produces bronchospasm. Individuals with normal lung function are unlikely to be affected, but smokers and others with lung disease can develop serious breathing difficulties.  $\beta$ -Blockers can contribute to heart failure in susceptible individuals, such as those with compensated heart failure, acute myocardial infarction, or cardiomegaly. Abrupt cessation of  $\beta$ -blockers can also exacerbate coronary heart disease in susceptible patients, producing angina or, potentially, myocardial infarction (see Hoffman and Lefkowitz 1996 for details).

In individuals with normal heart function, bradycardia produced by  $\beta$ -blockers is insignificant; however, in patients with conduction defects or when combined with other drugs that impair cardiac conduction,  $\beta$ -blockers can contribute to serious conduction problems.

$\beta$ -Blockers can block the tachycardia associated with hypoglycemia, eliminating this warning sign in patients with diabetes.  $\beta_2$  blockade also can inhibit glycogenolysis and glucose mobilization, interfering with recovery from hypoglycemia (Hoffman and Lefkowitz 1996).

$\beta$ -Blockers can impair exercise performance and produce fatigue, insomnia, and major depressive disorder. However, the development of major depressive disorder probably only occurs in individuals with a predisposition to developing depression.

**Drug-drug interactions.**  $\beta$ -Blockers can have significant interactions with other drugs. Chlorpromazine in combination with propranolol may increase the blood levels of both drugs. Additive effects on cardiac conduction and blood pressure can occur when  $\beta$ -blockers are combined with drugs having similar effects (e.g., calcium channel blockers). Phenytoin, phenobarbital, and rifampin increase the clearance of propranolol. Cimetidine increases propranolol blood levels by decreasing hepatic metabolism. Theophylline clearance is reduced by propranolol. Aluminum salts (antacids), cholestyramine, and colestipol may reduce the absorption of  $\beta$ -blockers (Hoffman and Lefkowitz 1996).

# Benzodiazepines for Medication-Induced Dystonia

## History and Discovery

Diazepam was initially shown to be effective in the treatment of restless legs syndrome (Ekbom syndrome), which resembles the physical movements of akathisia (Ekbom 1965). Subsequently, diazepam, lorazepam, and clonazepam were reported to be beneficial for medication-induced akathisia (Adler et al. 1985; Donlon 1973; Kutcher et al. 1987). Clonazepam also has been reported to be beneficial for drug-induced dystonia (O'Flanagan 1975) and TD (Thaker et al. 1987).

## Mechanism of Action

All benzodiazepines promote the binding of  $\gamma$ -aminobutyric acid (GABA) to GABA<sub>A</sub> receptors, magnifying the effects of GABA. The mechanism of action regarding improvement of EPS is unknown, but it may be related to augmentation of the inhibitory GABAergic effect (Hobbs et al. 1996). For a complete discussion of the properties of benzodiazepines, see Chapter 22 in this volume, "Benzodiazepines," by Sheehan.

## Indications

Benzodiazepines have FDA approval for use in treatment of anxiety disorders, agoraphobia, insomnia, and seizure disorders; management of alcohol withdrawal; anesthetic premedication; and skeletal muscle relaxation; however, they are not approved for use in treating any type of EPS. As noted earlier, a few initial reports have indicated that benzodiazepines are beneficial for the treatment of akathisia. Other studies also have reported similar benefit (Bartels et al. 1987; Braude et al. 1983; Gagrut et al. 1978; Horiguchi and Nishimatsu 1992; Kutcher et al. 1989; Pujalte et al. 1994).

Clonazepam has been reported to be effective in the treatment of TD (Bobruff et al. 1981; Thaker et al. 1990). Dosages of 1–10 mg/day were used in the first study, although the optimal dosage was found to be 4 mg/day, with many patients unable to tolerate higher dosages. In the second study, dosages of 2–4.5 mg/day were used, and tolerance developed after 5–8 months.

Although some of the studies were limited by short duration and by the small number of subjects also receiving other antiparkinsonian agents, the overall conclusion was that benzodiazepines probably have some efficacy in the treatment of akathisia and TD. However, the potential problems associated with the chronic use of benzodiazepines (i.e., tolerance and abuse) need to be kept in mind.

Lorazepam (intermediate-acting) and clonazepam (long-acting) are the two primary benzodiazepines that have been studied in the treatment of EPS. Because of its long duration of action, clonazepam often can be given once a day. Lorazepam has the advantage of having no active metabolites, which eliminates potential side effects and toxicity.

# Botulinum Toxin for Medication-Induced Dystonia

## History and Discovery

Botulinum toxin, produced by *Clostridium botulinum*, causes botulism when ingested. The first clinical use of the toxin was in the treatment of childhood strabismus (Scott 1980). The first focal dystonia treated was blepharospasm (Elston 1988). Botulinum toxin has been subsequently used to treat several other conditions associated with excessive muscle activity, including medication-induced dystonias (Hughes 1994).

## Structure-Activity Relations

There are seven immunologically distinct botulinum toxins (Simpson 1981). Type A is the primary type used clinically (Hambleton 1992). Type F and possibly type B also have clinical utility, but they have much shorter durations of action ( $\leq 3$  weeks, compared with  $\geq 3$  months for type A) (Borodic et al. 1996). The toxin is quantified by bioassay and is expressed as mouse units, which refers to the dose that is lethal to 50% of animals following intraperitoneal injection (Quinn and Hallet 1989).

## Pharmacological Profile

Botulinum toxin binds to cholinergic motor nerve terminals, preventing release of acetylcholine and producing a functionally denervated muscle. The prevention of acetylcholine release occurs within a few hours, but the clinical effect does not occur for 1–3 days. The innervation gradually becomes restored, although the number or size of active muscle fibers is reduced (Odergren et al. 1994).

## Pharmacokinetics and Disposition

After binding to the presynaptic nerve terminal, the toxin is taken into the nerve cell and is metabolized. When antibodies are present, the toxin is metabolized by immunological processes.

## Mechanism of Action

Botulinum toxin acts presynaptically to prevent the release of acetylcholine at the neuromuscular junction. This produces a functional chemical denervation and paralysis of the muscle. When botulinum toxin is used clinically, the aim is to reduce the excessive muscle activity without producing significant weakness (Hughes 1994).

## Indications

The FDA has approved the use of botulinum toxin for strabismus, blepharospasm, and other facial nerve disorders (see Jankovic and Brin 1991). Botulinum toxin has been used to treat focal neuroleptic-induced dystonias that may occur as part of TD, including laryngeal dystonia (Blitzer and Brin 1991) and refractory torticollis (Kaufman 1994). For laryngeal dystonia, the toxin is injected percutaneously through the cricothyroid membrane into the thyroarytenoid muscle bilaterally. The response rate is 80%–90%, and the effect lasts 3–4 months and sometimes longer. Botulinum treatment of tardive cervical dystonia has been found to be effective; the observed improvement is similar to the improvement seen in the treatment of idiopathic

cervical dystonia, although patients with tardive cervical dystonia required higher doses ([Brashear et al. 1998](#)).

### Side Effects and Toxicology

The major potential side effect of botulinum toxin is focal weakness in the muscle group injected, an effect that is usually dose dependent. This effect is generally temporary, given the mechanism of action. Transient weakness can occur through diffusion of the toxin into surrounding noninjected muscles ([Hughes 1994](#)).

Antibodies to the toxin can occur and thus can prevent a therapeutic response, particularly during subsequent treatments. The two main factors that apparently contribute to the development of antibodies are early age at first treatment with the toxin and total cumulative dose ([Jankovic and Schwartz 1995](#)). Some patients with antibodies will respond to other botulinum serotypes, such as type F ([Greene and Fahn 1993](#)). Local skin reactions also can occur. Some degree of muscle atrophy is apparent in injected muscles ([Hughes 1994](#)). Reinnervation usually takes place over the course of 3–4 months ([Odergren et al. 1994](#)).

Botulinum toxin has no known contraindications. Because the effect on the fetus is unknown, use of the toxin is not recommended during pregnancy. In conditions in which there are neuromuscular junction disorders, such as myasthenia gravis, patients could theoretically experience increased weakness. The long-term effects are unknown ([Hughes 1994](#)).

### Drug-Drug Interactions

Botulinum toxin has no known interactions with other drugs.

## Vitamin E (Alpha-Tocopherol) for Tardive Dyskinesia

### History and Discovery

Vitamin E was proposed as a treatment for TD after it was noted that a neurotoxin in rats induced an irreversible movement disorder and axonal damage similar to that caused by vitamin E deficiency. It was proposed that chronic antipsychotic use might produce free radicals, which would contribute to neurological damage and TD, and that the antioxidant effect of vitamin E could attenuate the damage ([Cadet et al. 1986](#)).

### Indications

The only known indication for vitamin E is treatment of vitamin E deficiency, which almost always results from malabsorption syndromes or abnormal transport, such as with abetalipoproteinemia ([Bieri and Farrell 1976](#)).

Early studies of vitamin E treatment of TD reported a range of results from general benefit ([Adler et al. 1993](#); [Dabiri et al. 1994](#); [Lohr et al. 1988](#)) to benefit only in subjects with TD of less than 5 years' duration ([Egan et al. 1992](#); [Lohr and Caligiuri 1996](#)) to no benefit ([Schmidt et al. 1991](#); [Shrqui et al. 1992](#)). Subsequently, a major double-blind study comparing vitamin E with placebo found that vitamin E was no more beneficial than placebo ([Adler et al. 1999](#)). There were no significant

effects of vitamin E on total scores or subscale scores for the Abnormal Involuntary Movement Scale (AIMS; [Guy 1976](#)), on electromechanical measures of dyskinesia, or on scores for four other scales measuring dyskinesia. The authors concluded that there was no evidence for efficacy of vitamin E in the treatment of TD ([Adler et al. 1999](#)).

The use of vitamin E supplementation is not without risk. A meta-analysis of high-dosage vitamin E supplementation trials showed a statistically significant association between vitamin E dosage and all-cause mortality, with increased risk for dosages greater than 150 IU/day (E.R. [Miller et al. 2005](#)). Given the lack of data showing consistent effectiveness for TD, we do not recommend that vitamin E be used for this purpose.

### Side Effects and Toxicology

Side effects are minimal when vitamin E is given orally. High levels of vitamin E can exacerbate bleeding abnormalities that are associated with vitamin K deficiency. Dosages of up to 3,200 mg/day in studies for other conditions have been used without significant adverse effects ([Kappus and Diplock 1992](#)). The only known drug interactions are with vitamin K (when it is being given for a deficiency) and bleeding abnormalities and possibly with oral anticoagulants. High dosages of vitamin E can exacerbate the coagulation abnormalities in both cases and therefore are contraindicated ([Kappus and Diplock 1992](#)).

---

## Antipsychotic Dopamine-Receptor Blockade and EPS

---

No drug with antipsychotic activity has been identified that does not have significant affinity for D<sub>2</sub> dopamine receptors. D<sub>2</sub> receptor blockade is the pharmacodynamic property of all antipsychotics, and without this property, a drug will not show any antipsychotic effects. This is true for both typical (first-generation) and atypical (second-generation) antipsychotics. The antipsychotic effects of typical antipsychotics are directly related to the degree of D<sub>2</sub> receptor blockade. The antipsychotic effects of atypical antipsychotics, however, are more complicated ([Meltzer 2002](#)).

All of the atypical antipsychotics are potent serotonin type 2A (5-HT<sub>2A</sub>) receptor antagonists and relatively weak D<sub>2</sub> receptor antagonists compared with the typical antipsychotics (except for cariprazine, which has relatively weak blockade of 5-HT<sub>2A</sub> receptors compared with the other atypical antipsychotics [[Gyertyán et al. 2011](#)]). The high ratio of 5-HT<sub>2A</sub> receptor blockade to striatal D<sub>2</sub> receptor blockade that characterizes clozapine is thought to contribute to its lack of EPS ([Meltzer et al. 1989](#)).

Blockade of 5-HT<sub>2A</sub> and dopamine receptors was first labeled in 1989 as a pharmacodynamic mechanism that differentiated conventional from second-generation antipsychotics ([Meltzer 1989](#)). [Meltzer \(2002\)](#) defined atypical

antipsychotics as drugs showing a higher affinity for 5-HT<sub>2A</sub> receptors than for D<sub>2</sub> receptors and a lower affinity for D<sub>2</sub> receptors than that seen with conventional antipsychotics. For the nigrostriatal dopaminergic pathway, one proposed model suggested that blockade of 5-HT<sub>2A</sub> receptors would lead to increased output of dopaminergic neurons into the striatum, causing an antipsychotic drug to be displaced from its binding to D<sub>2</sub> receptors. It was theorized that this displacement could decrease the risk of EPS development ([Horacek et al. 2006](#)).

---

## Treatment Approaches to Specific Types of EPS

---

### Acute Dystonic Reactions

Intramuscular anticholinergics are the treatment of choice for ADRs. Benztropine 2 mg or diphenhydramine 50–100 mg generally will produce complete resolution within 20–30 minutes, with a second dose repeated after 30 minutes if complete recovery does not occur. Benztropine has been shown to resolve ADRs in less time than diphenhydramine ([Lee 1979](#)). Starting a standing dose of an antiparkinsonian agent afterward is generally not necessary. ADRs do not recur, unless large dosages of high-potency antipsychotics are being used or unless the dosage is increased. A more complete discussion of prophylaxis is provided in the section “Prophylactic Use of Antiparkinsonian Agents” later in this chapter.

### Parkinsonism and Akathisia

The initial steps in treatment of parkinsonism ([Table 35-3](#)) and of akathisia (also referred to here as EPS) are identical: evaluating the dosage and type of antipsychotic. It has been shown that an increase in dosage beyond the neuroleptic threshold will not produce any greater therapeutic benefit but will increase EPS ([Angus and Simpson 1970a](#); [Baldessarini et al. 1988](#); [McEvoy et al. 1991](#)). It also has been found that EPS frequently can be eliminated with a reduction in dosage or a change to a lower-potency antipsychotic ([Braude et al. 1983](#); [Stratas et al. 1963](#)).

---

**TABLE 35-3. Treatment of parkinsonism**

---

Step	Action
1	Reduce dosage of antipsychotic, if clinically possible.
2	Substitute a lower-potency antipsychotic, or carry out step 8.
3	Add an anticholinergic agent.
4	Titrate anticholinergic to maximum dosage tolerated.

Step	Action
5	Add amantadine in combination with anticholinergic or as a single agent.
6	Add a benzodiazepine or a $\beta$ -blocker.
7	In severe cases of extrapyramidal side effects, stop antipsychotic temporarily and repeat process, beginning with step 3.
8	Substitute antipsychotic with atypical antipsychotic or clozapine.

If this approach does not resolve EPS, or if a lower-potency antipsychotic cannot be substituted, the addition of an anticholinergic drug is the next step. Maximum therapeutic response occurs in 3–10 days, with more severe EPS taking a longer time to respond (DiMascio et al. 1976; Fann and Lake 1976). The anticholinergic dose should be increased until EPS are alleviated or until an unacceptable degree of anticholinergic side effects is obtained. Akathisia frequently does not respond as well to anticholinergic medications and amantadine as do parkinsonism and ADRs (DiMascio et al. 1976). Akathisia is more likely to be responsive to anticholinergic agents if symptoms of parkinsonism are also present (Fleischhacker et al. 1990).

If EPS remain uncontrolled, amantadine can be either added to the regimen or substituted as a single agent. The next step would be the addition of a benzodiazepine or a  $\beta$ -blocker, although fewer data support both of these treatments.

In the case of severe EPS, the antipsychotic should be temporarily stopped, because severe EPS may be a risk factor for the development of neuroleptic malignant syndrome (Levinson and Simpson 1986).

Additional drugs have been studied or suggested as treatments for akathisia. The data supporting the use of amantadine for the treatment of akathisia are limited. Clonidine has been studied in a small number of patients, but its benefit was limited by sedation and hypotension (Fleischhacker et al. 1990). Sodium valproate was reported to have had no significant effect on akathisia and was found to increase parkinsonism (Friis et al. 1983).

### Atypical Antipsychotics and Risk of Parkinsonism and Akathisia

As experience with the use of atypical antipsychotics has increased, further data have been obtained about the risk of EPS. A review of studies involving atypical antipsychotics in which EPS were assessed found that EPS, especially akathisia, did occur with atypical antipsychotics, although the frequency was not as high as with typical antipsychotics. Risk factors include the use of high dosages of medication, high-potency atypical antipsychotics, combinations of atypical antipsychotics with other psychotropics, bipolar depression, palliative care settings, and substance abuse with psychosis (Kumar and Sachdev 2009).

Gao et al. (2008) conducted a review of studies of patients with schizophrenia or bipolar disorder. The studies included both typical and atypical antipsychotics. Haloperidol significantly increased the risk for akathisia, overall EPS, and anticholinergic use in both mania and schizophrenia, with a larger magnitude in mania. Among atypical antipsychotics, only ziprasidone significantly increased the

risk for overall EPS and anticholinergic use in both mania and schizophrenia, again with larger differences in mania. Patients with mania treated with risperidone had a significantly increased risk for overall EPS and anticholinergic use. Patients taking aripiprazole for bipolar mania and bipolar depression had increased risk for akathisia. Patients with bipolar depression treated with quetiapine had an increased risk for overall EPS. The authors concluded that bipolar depressed patients are at the greatest risk for acute antipsychotic-induced movement disorders.

Data from the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) studies showed no clinically significant difference in the incidence of parkinsonian symptoms and akathisia between the atypical agents and a moderate-potency typical agent, perphenazine. Although a statistically significantly greater number of patients taking perphenazine than patients taking atypical antipsychotics discontinued treatment because of EPS (8% vs. 2%–4%), the EPS incidence was low and of limited clinical significance (D.D. [Miller et al. 2005](#)).

In the past, if a patient receiving a typical antipsychotic developed severe parkinsonism or akathisia and did not respond to antiparkinsonian treatment, the recommended strategy was to switch to an atypical antipsychotic. Now the recommendation can be made to consider the use of a less potent typical antipsychotic as one of the options for treatment, along with possibly changing to an atypical agent.

For severe refractory EPS that have not responded to standard treatments, the use of clozapine specifically to treat the EPS is indicated ([Casey 1989](#)). This is particularly true for akathisia, given its significant negative correlation with the outcome of schizophrenia. This is also true for patients who do not have any psychotic symptoms, if the EPS are judged to be severe enough to be disabling or potentially life-threatening, such as laryngeal dystonia.

**Clozapine.** Patients taking clozapine (FDA approved in 1989) were found to have significantly less parkinsonism compared with patients taking a combination of chlorpromazine and an antiparkinsonian agent (benztropine) ([Kane et al. 1988](#)). The prevalence and incidence of akathisia also were shown to be lower in patients taking clozapine than in patients taking other first- or second-generation antipsychotics ([Chengappa et al. 1994](#); [Chouinard et al. 1993](#); [Kurz et al. 1995](#); [Stanilla et al. 1995](#)). Clozapine is covered in detail elsewhere in this volume (see [Chapter 25](#), “Clozapine,” by [Marder and Yang](#)).

**Other atypical antipsychotics.** The atypical antipsychotics approved for use in the United States after clozapine were also shown either to produce EPS at rates similar to those seen with haloperidol (risperidone, olanzapine, quetiapine, ziprasidone, asenapine, and iloperidone) or to produce EPS at rates comparable to those seen with placebo (aripiprazole, paliperidone, cariprazine, and brexpiprazole).

*Risperidone.* Risperidone (approved in 1993) was the first atypical antipsychotic to become available after clozapine ([Claus et al. 1992](#)). At lower dosages (4–6 mg/day), risperidone usually does not produce significant parkinsonism, but unlike clozapine, it can produce significant parkinsonism at higher dosages ([Chouinard et al. 1993](#)). In initial studies comparing risperidone with haloperidol, the extrapyramidal scores for

patients receiving risperidone (6 mg once daily) were not significantly different from the scores of patients receiving placebo. Risperidone can cause ADRs, and patients with severe EPS at baseline were more likely to develop EPS when taking risperidone ([Simpson and Lindenmayer 1997](#)). Risperidone is covered in detail elsewhere in this volume (see [Chapter 28, "Risperidone and Paliperidone,"](#) by [Hill and Goff](#)).

*Olanzapine.* Olanzapine (approved in 1996) has been shown to have an antipsychotic effect comparable to that of haloperidol while producing less dystonia, parkinsonism, and akathisia ([Tollefson et al. 1997](#)). The reduced incidence of EPS was observed across the entire therapeutic dosage range of 5–24 mg/day. Olanzapine is covered in detail elsewhere in this volume (see [Chapter 26, "Olanzapine,"](#) by [Silberschmidt et al.](#)).

*Quetiapine.* Quetiapine (approved in 1997) has been found to have antipsychotic activity comparable to that of haloperidol at dosages ranging from 150 to 750 mg/day while producing parkinsonism at a level similar to that produced by placebo across the entire dosage range ([Arvanitis and Miller 1997](#); [Small et al. 1997](#)). Most patients had no significant changes in AIMS scores from baseline to the end of a 6-week period of treatment. Quetiapine is covered in detail elsewhere in this volume (see [Chapter 27, "Quetiapine,"](#) by [Buckley et al.](#)).

*Ziprasidone.* Ziprasidone (approved in 2001) was compared with haloperidol in a double-blind, dose-ranging trial and found to have comparable antipsychotic effect at higher dosages. Benzotropine use at any time during the study was less frequent with the highest dosage of ziprasidone (160 mg/day) than with haloperidol (15% vs. 53%) ([Goff et al. 1998](#)). Studies of ziprasidone found no significant differences in baseline-to-endpoint mean changes on Simpson-Angus Scale ([Simpson and Angus 1970](#)) and AIMS scores between placebo and ziprasidone (40–160 mg/day) ([Keck et al. 2001](#)). Ziprasidone is covered in detail elsewhere in this volume (see [Chapter 30, "Ziprasidone,"](#) by [Newcomer et al.](#)).

*Aripiprazole.* Aripiprazole (approved in 2002) was found to be comparable to risperidone in antipsychotic effect while producing EPS comparable to those seen with placebo ([Kane et al. 2002](#); [Potkin et al. 2003](#)). Aripiprazole is covered in detail elsewhere in this volume (see [Chapter 29, "Aripiprazole and Brexpiprazole,"](#) by [Gonzalez and Strassnig](#)).

*Paliperidone.* Extended-release paliperidone (approved in 2006) was found to have an incidence of EPS nearly comparable to that of placebo (7% vs. 3%) at a dosage range of 3–15 mg/day ([Kramer et al. 2007](#)). Paliperidone is covered in detail elsewhere in this volume (see [Chapter 28, "Risperidone and Paliperidone,"](#) by [Hill and Goff](#)).

*Asenapine.* Asenapine (approved in 2009) was evaluated in a 6-week double-blind, placebo- and active-controlled (haloperidol) trial of 458 patients with acute schizophrenia. Patients were given asenapine (5 mg or 10 mg twice a day),

haloperidol (4 mg twice a day), or placebo. The incidence of EPS for asenapine was 15% for 5 mg twice a day and 18% for 10 mg twice a day, 34% for haloperidol, and 10% for placebo ([Kane et al. 2010](#)).

In a study of 488 patients with manic or mixed episodes of bipolar disorder, patients receiving asenapine (5–10 mg twice a day) were compared with those receiving olanzapine (5–20 mg/day) or placebo. The incidence of EPS was found to be 10.3% for asenapine, 6.8% for olanzapine, and 3.1% for placebo ([McIntyre et al. 2010](#)).

Asenapine is covered in detail elsewhere in this volume (see [Chapter 31](#), “Asenapine,” by Citrome).

*Lurasidone.* Lurasidone (approved in 2009) was compared with placebo in a 6-week double-blind study of 180 patients with acute schizophrenia. Patients receiving lurasidone 80 mg/day were found to have no clinically significant differences in the incidence of EPS compared with patients receiving placebo ([Nakamura et al. 2009](#)). Lurasidone is covered in detail elsewhere in this volume (see [Chapter 33](#), “Lurasidone,” by Harvey).

*Iloperidone.* Iloperidone (approved in 2009) was evaluated from the pooled results of three double-blind studies of 1,912 patients with schizophrenia. Patients received iloperidone (4–24 mg/day), haloperidol (15 mg/day), risperidone (4–8 mg/day), or placebo. The incidences of akathisia and EPS were lower with iloperidone than with risperidone and haloperidol and generally were similar to the incidences with placebo ([Potkin et al. 2008](#)). Iloperidone is covered in detail elsewhere in this volume (see [Chapter 32](#), “Iloperidone,” by Buckley et al.).

*Brexpiprazole.* Brexpiprazole was approved in 2015 for the treatment of schizophrenia. A double-blind study compared brexpiprazole (daily dosages of 0.25, 2, or 4 mg) with placebo in patients with acute schizophrenia. The incidence of akathisia was relatively low for both placebo (2%) and brexpiprazole 0.25 mg (0%), 2 mg (7%), and 4 mg (7%) ([Correll et al. 2015](#)). Brexpiprazole is covered in detail elsewhere in this volume (see [Chapter 29](#), “Aripiprazole and Brexpiprazole,” by Gonzalez and Strassnig).

*Cariprazine.* Cariprazine was approved in 2015 for the treatment of schizophrenia and bipolar disorder in adults ([Sachs et al. 2015](#)). Cariprazine was evaluated in a 6-week double-blind, placebo- and active-controlled (aripiprazole) study in patients with acute schizophrenia. Patients were assigned to cariprazine 3 or 6 mg/day, aripiprazole 10 mg/day, or placebo. The only treatment-emergent adverse event that occurred in more than 5% of the patients was akathisia in the 6 mg/day cariprazine group (15%). The incidence was significantly greater than the incidence with placebo (4.6%;  $P=0.0034$ ). The incidence for the 3 mg/day group was 7%. The incidence for aripiprazole was 7% ([Durgam et al. 2015](#)). Cariprazine is covered in detail elsewhere in this volume (see [Chapter 34](#), “Cariprazine,” by Albrahim et al.).

## Tardive Dyskinesia and Tardive Dystonia

Historically, TD has been refractory to treatment, which explains the large number of drugs used in attempts to alleviate the condition. Treatments investigated have included, but are not limited to, noradrenergic antagonists (propranolol and clonidine), antagonists of dopamine and other catecholamines, dopamine agonists, catecholamine-depleting drugs (reserpine and tetrabenazine), GABAergic drugs, cholinergic drugs (deanol, choline, and lecithin), catecholaminergic drugs ([Kane et al. 1992](#)), calcium channel blockers ([Cates et al. 1993](#)), and selective monoamine oxidase inhibitors (selegiline) ([Goff et al. 1993](#)). Based on the investigations of these drugs, the American Psychiatric Association Task Force on Tardive Dyskinesia concluded that there is no consistently effective treatment for TD ([Kane et al. 1992](#)).

Evaluating the effects of any treatment for TD has inherent difficulties. These include the variability of clinical raters ([Bergen et al. 1984](#)), the variability of placebo response ([Sommer et al. 1994](#)), and the diurnal and longitudinal variability of TD ([Hyde et al. 1995](#); [Stanilla et al. 1996](#)). The degree of improvement needs to be greater than the sum of such variations to show an actual benefit.

The first step in evaluating TD is to determine the type of antipsychotic agent that is being used. If a typical antipsychotic is necessary, it is important to use the lowest dosage possible ([Simpson 2000](#)). Second, if anticholinergic antiparkinsonian medications are being used, the patient should be gradually weaned from these medications and the medications then discontinued. In contrast to their effect on other extrapyramidal movements, anticholinergic medications will make TD movements worse (see [Greil et al. 1984](#); [Jeste and Wyatt 1982](#)).

Some drugs have been shown to have some benefit in the treatment of TD, but they have limitations. Clonazepam has been reported to reduce the movements of TD for up to 9 months, although tolerance to the benefits developed ([Thaker et al. 1990](#)). Additional limitations are the inherent problems associated with chronic use of a benzodiazepine. Botulinum toxin is beneficial for treating localized tardive dystonias, particularly laryngeal and cervical dystonias ([Hughes 1994](#)). The injections need to be repeated every 3–6 months, and botulinum toxin is not a general treatment for TD. Vitamin E has not consistently been shown to be beneficial in all studies, and a large long-term double-blind study found no benefit for vitamin E compared with placebo ([Adler et al. 1999](#)).

Valbenazine (NBI-98854) is a vesicular monoamine transporter inhibitor that is actively being studied in the treatment of TD. Tetrabenazine, the original agent in this class, is effective in treating movement disorders but has important dosing and safety limitations. In a recent report of a Phase II study in 102 patients, valbenazine was highly statistically significantly more effective than placebo in improving TD ([O'Brien et al. 2016](#)), with apparently better safety and tolerability and greater ease of administration relative to tetrabenazine. Valbenazine is currently being investigated in pivotal Phase III trials and has been granted a Breakthrough Therapy designation by the FDA ([Müller 2015](#)).

Tardive dystonia also tends to be resistant to treatment; however, unlike TD, it may respond to anticholinergic medications ([Wojcik et al. 1991](#)) and to reserpine ([Kang et al. 1988](#)).

## **Atypical Antipsychotics and Risk of Tardive Syndromes**

Clozapine has been shown to decrease the symptoms of TD ([Simpson and Varga 1974](#); [Simpson et al. 1978](#)), with the greatest improvement occurring in cases of severe TD and tardive dystonia ([Lieberman et al. 1991](#)). These findings have been replicated and suggest that clozapine is unlikely to cause TD ([Chengappa et al. 1994](#); [Kane et al. 1993](#)). The disadvantages to clozapine are the potential side effects of agranulocytosis and seizures and the need for regular blood monitoring.

More data indicating the potential benefit of the other novel antipsychotics in the prevention and treatment of TD are being reported.

In a prospective double-blind study of patients with schizophrenia receiving treatment with either olanzapine or haloperidol and followed for up to 2.6 years, the risk for the development of TD with olanzapine was significantly decreased. The 1-year risk was 0.52% for olanzapine and 7.45% for haloperidol ([Beasley et al. 1999](#)).

A prospective study examined the incidence of emergent dyskinesia in middle-aged to elderly patients (mean age=66 years) taking haloperidol or low-dosage risperidone (mean total daily dosage for both medications=1 mg/day). Compared with the patients taking haloperidol, those taking risperidone were significantly less likely to develop TD ([Jeste et al. 1999](#)). A double-blind prospective study comparing 397 patients with schizophrenia on stable dosages of antipsychotics who were randomly assigned to switch to either risperidone or haloperidol and followed up for at least a year found that only 1 of the patients receiving risperidone developed dyskinetic movements, compared with 5 of the patients receiving haloperidol ([Csernansky et al. 2002](#)).

The data regarding the long-term effect of atypical antipsychotics in causing TD are more limited; however, any drug that is less likely to produce EPS is probably less likely to produce TD.

The best treatment for TD is prevention. Of the 1,460 subjects involved in the CATIE study, D.D. [Miller et al. \(2005\)](#) found 212 to have probable TD by Schooler-Kane criteria. They found that subjects with TD were older, had a longer duration of receiving antipsychotic medications, and were more likely to have been receiving a typical antipsychotic and an anticholinergic agent. They also found that substance abuse significantly predicted TD, as well as subjects with higher ratings of psychopathology, parkinsonian symptoms, and akathisia (D.D. [Miller et al. 2005](#)).

Patients with TD who are taking typical antipsychotics are candidates for switching to an atypical antipsychotic. In the case of severe TD or dystonia that has been unresponsive to other treatment, the use of clozapine is indicated ([Simpson 2000](#)).

---

## Prophylactic Use of Antiparkinsonian Agents

---

### Indications and Efficacy

Prophylactic use of antiparkinsonian agents to prevent EPS is a common but not completely accepted practice. Most controlled prospective studies regarding prophylactic use of antiparkinsonian medication have shown that prophylaxis can be beneficial for certain patients who are at high risk for developing ADRs but that it is

not beneficial in routine use across all patient groups ([Hanlon et al. 1966](#); [Sramek et al. 1986](#)). Several retrospective studies also have found that the need for prophylaxis of EPS is limited ([Swett et al. 1977](#)). The retrospective studies that identified a greater benefit from prophylaxis involved the use of high antipsychotic dosages ([Keepers et al. 1983](#); [Stern and Anderson 1979](#)).

[Table 35-4](#) summarizes the risk factors for developing ADRs, which include younger age (<35 years), higher dosages of antipsychotic, higher potency of antipsychotic, intramuscular route of delivery, (possibly) male sex ([Sramek et al. 1986](#)), and a history of ADRs from a similar antipsychotic ([Keepers and Casey 1991](#)). The use of cocaine also has been suggested as a possible risk factor ([van Harten et al. 1998](#)).

<b>TABLE 35-4. Risk factors for acute dystonic reactions</b>
High-potency antipsychotics
Haloperidol
Fluphenazine
Trifluoperazine
High dosages
Younger age (<35 years) <sup>a</sup>
Intramuscular route of delivery
Previous dystonic reaction to similar antipsychotic and dosage
Male sex (?)

<sup>a</sup>Approaches 100% at age <20 years.

## Withdrawal of Prophylactic Agents

Studies examining withdrawal of antiparkinsonian agents have found that not all subjects redevelop EPS when these agents are discontinued. In the first study to report this serendipitous finding ([Cahan and Parrish 1960](#)), patients were being withdrawn from benztropine in preparation for a trial of a new antiparkinsonian agent. The discovery that only 20% of the patients developed recurrent parkinsonian symptoms following withdrawal led the study authors to suggest that antiparkinsonian agents should be withdrawn after 2 months and that their use should be resumed only in patients who re-develop EPS ([Cahan and Parrish 1960](#)).

Other withdrawal studies have reported wide-ranging rates of EPS recurrence. Differences in rates of recurrence are related to the varying methodologies involved in the studies, including methods of rating and the initial reason for treatment with anticholinergics—prophylaxis or active treatment ([Ananth et al. 1970](#)). The types, dosages, and combinations of antipsychotics used—the same factors that contribute to the initial development of EPS—also have been major factors in determining recurrence rates ([Baker et al. 1983](#); [McClelland et al. 1974](#)).

Almost all anticholinergic withdrawal studies have involved abrupt withdrawal of the anticholinergic medications. Abrupt, compared with gradual, withdrawal is more

likely to result in a return of EPS. Gradual withdrawal studies have found that a large percentage (up to 90%) of patients can be completely withdrawn from anticholinergic medications without developing EPS, and the remaining patients can have their EPS controlled with a considerably reduced dosage ([Double et al. 1993](#); [Ungvari et al. 1999](#)).

Patients are more likely to develop EPS on withdrawal of antiparkinsonian agents if the risk factors for developing EPS are present. If these risk factors are minimized, the rate of EPS recurrence is lowered.

Among patients who experience a recurrence of EPS, the EPS generally reappear within 2 weeks, and control is easily reestablished ([Klett and Caffey 1972](#)). Patients respond rapidly and often require smaller dosages of antiparkinsonian medications for control while continuing to take the same antipsychotic dosage ([McClelland et al. 1974](#)).

---

## Conclusion

---

The unique properties of chlorpromazine and other similarly active agents in ameliorating psychotic symptoms and producing parkinsonian side effects were described in the early 1950s by French psychiatrists. Theories soon arose regarding the relationship between these two properties. Recognition of the benefits of reducing parkinsonian side effects led to investigations of methods to reduce EPS and to the development of instruments to measure EPS.

The debate regarding the routine and prophylactic use of antiparkinsonian agents has continued since that time. It appears that prophylactic antiparkinsonian agents need to be used in some situations, but probably with less frequency and for briefer periods of time than has generally been the practice. The trend toward the use of lower dosages of antipsychotics should also lead to a decreased need for the use of antiparkinsonian agents.

Finally, the advent of atypical antipsychotic agents has opened a new chapter in both the treatment and the prevention of EPS and suggests that in the future, EPS will be less of a problem than they have been in the past.

A summary of an American Psychiatric Association Task Force report on TD suggested that a “deliberate and sustained effort must be made to maintain patients on the lowest effective amount of drug and to keep the treatment regimen as simple as possible” ([Baldessarini et al. 1980](#), p. 1168), and that anticholinergic drugs should be discontinued as soon as possible. Apart from a greater emphasis on avoiding the initial use of antiparkinsonian agents, this statement remains valid.

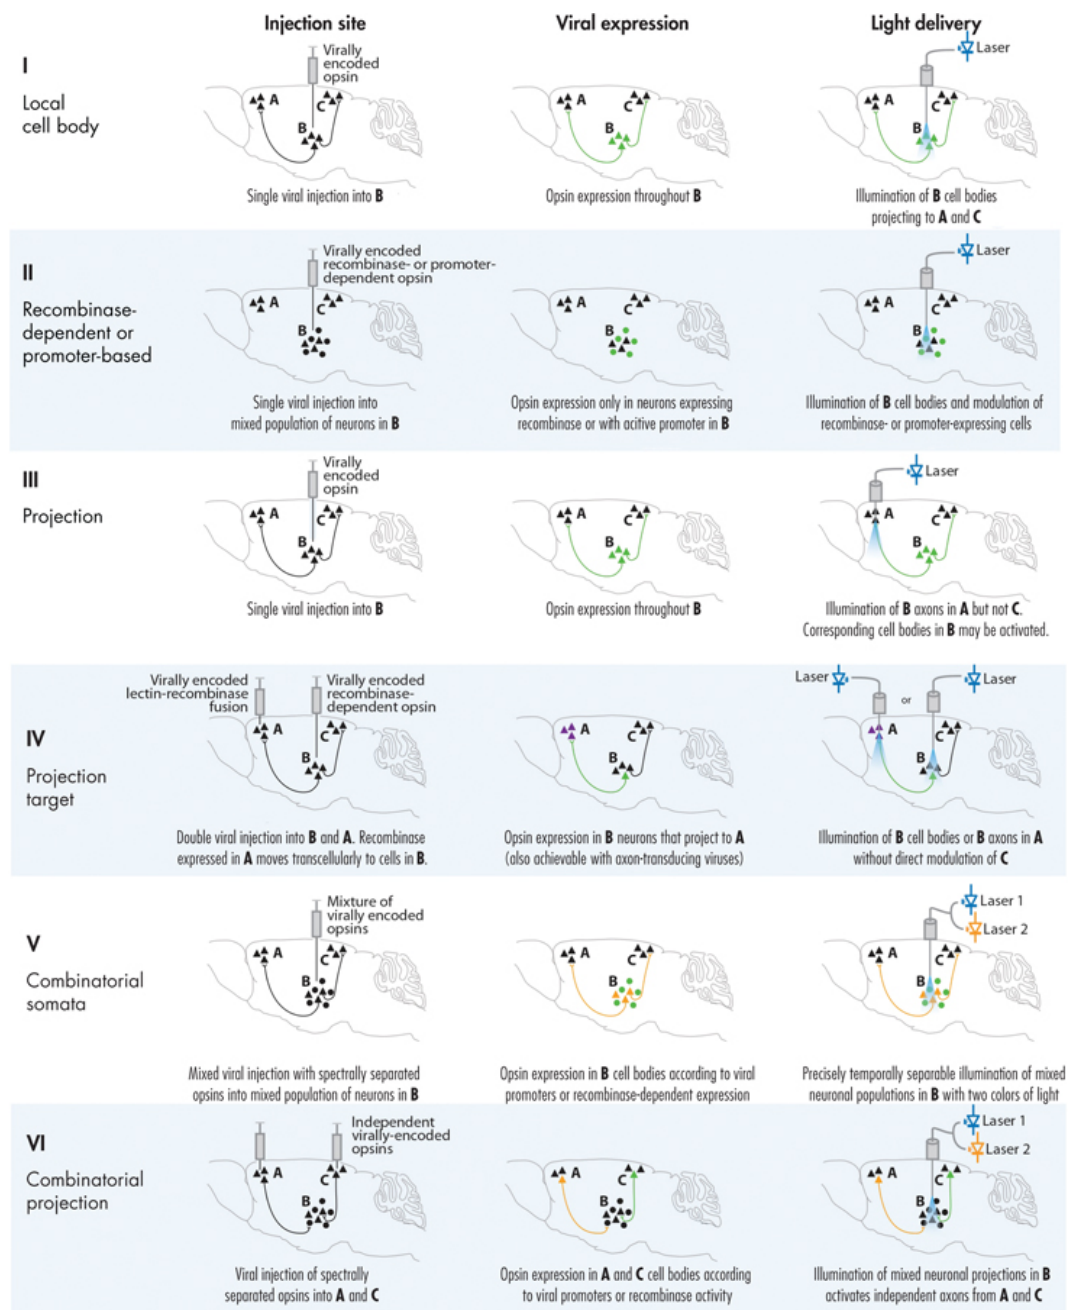

**PLATE 1.** (Figure 1-7) Cas9-based systems for altering gene sequence or expression.

(A) Cas9 nuclease creates double-strand breaks at DNA target sites with complementarity to the 5' end of a gRNA. (B) Cas9 nickase created by mutation of the RuvC nuclease domain with a D10A mutation. This nickase cleaves only the DNA strand that is complementary to and recognized by the gRNA. (C) Cas9 nickase created by mutation of the HNH nuclease domain with an H840A

mutation. This nickase cleaves only the DNA strand that does not interact with the small RNA. **(D)** Paired nickase strategy for improving Cas9 specificity. D10A Cas9 nickase directed by a pair of appropriately oriented gRNAs leads to induction of two nicks that, if introduced simultaneously, would be expected to generate a 5' overhang. **(E)** Catalytically inactive or "dead" Cas9 (dCas9) that can be recruited by a gRNA without cleaving the target DNA site. **(F)** Catalytically inactive dCas9-bearing dual D10A/H840A mutations fused to a heterologous effector domain. Cas9=CRISPR-associated protein 9 nuclease from *Streptococcus pyogenes*; CRISPR=clustered, regularly interspaced, short palindromic repeat; gRNA=guide RNA; PAM (NGG)=protospacer adjacent motif (sequence 5'-NGG-3', where "N" is any nucleobase followed by two guanine ("G") nucleobases).

## PLATES 2 AND 3. (Figure 1–9) Optogenetic manipulation of neural circuits.

**(I)** Direct stimulation of neuronal cell bodies is achieved by injecting virus at the target region and then implanting a light-delivery device above the injected region. Even this simple experiment can provide specificity with viruses that will not

transduce afferent axons and fibers of passage. **(II)** Additional cell-type specificity is attained either by cell-type-specific promoters in the viral vector or via a recombinase-dependent virus, injected in a transgenic animal expressing a recombinase such as Cre in specific cells, leading to specific expression of the transgene only in defined cell types. **(III)** Projection (axonal) targeting is achieved by viral injection at the region harboring cell bodies, followed by implantation of a light-delivery device above the target region containing neuronal processes from the virally transduced region; in this way, cell types are targeted by virtue of their projections. **(IV)** Projection termination labeling is a more refined version of projection targeting, in which cells are targeted by virtue of synaptic connectivity to the target region, with likely exclusion of cells whose axons simply pass through the region. Transcellular labeling using a recombinase-dependent system is shown. Viruses expressing Cre fused to a transneuronal tracer (lectin) are delivered at the synaptic target site, and a Cre-dependent virus is injected into the region with cell bodies. Cells that project to the Cre-injected area express the Cre-dependent virus and become light sensitive. This can also be achieved with axon terminal-transducing viruses, although without control over the postsynaptic cell type. **(V)** Expression of two opsins with different characteristics in one brain region using a combination of promoter- or Cre-based approaches. Light delivery to the somata is performed using two different wavelengths designed to minimize cross-activation. **(VI)** Projections from two different brain regions are differentially stimulated with two wavelengths matched to the respective opsins expressed upstream.

**PLATE 4.** (*Figure 2-1*) Major receptor subtypes in the central nervous system.

This figure depicts the four major classes of receptors in the CNS.

**(A) Ionotropic receptors.** These receptors comprise multiple protein subunits that are combined in such a way as to create a central membrane pore through this complex, allowing the flow of ions. This type of receptor has a very rapid response time (milliseconds). The consequences of receptor stimulation (i.e., excitatory or inhibitory) depend on the types of ions that the receptor specifically allows to enter the cell. Thus, for example,  $\text{Na}^+$  entry through the NMDA (*N*-methyl-D-aspartate) receptor depolarizes the neuron and brings about an excitatory response, whereas  $\text{Cl}^-$  efflux through the  $\gamma$ -aminobutyric acid type A ( $\text{GABA}_A$ ) receptor hyperpolarizes the neuron and brings about an inhibitory response. Illustrated here is the NMDA receptor regulating a channel permeable to  $\text{Ca}^{2+}$ ,  $\text{Na}^+$ , and  $\text{K}^+$  ions. The NMDA receptors also have binding sites for

glycine,  $\text{Zn}^{2+}$ , phencyclidine, MK801/ketamine, and  $\text{Mg}^{2+}$ ; these molecules are able to regulate the function of this receptor. **(B) *G protein-coupled receptors*** (GPCRs). The majority of neurotransmitters, hormones, and even sensory signals mediate their effects via seven transmembrane domain-spanning receptors that are G protein-coupled. The amino terminus of the G protein is on the outside of the cell and plays an important role in the recognition of specific ligands; the third intracellular loop and carboxy terminus of the receptor play an important role in coupling to G proteins and are sites of regulation of receptor function (e.g., by phosphorylation). All G proteins are heterotrimers (consisting of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits). The G proteins are attached to the membrane by isoprenoid moieties (fatty acid) via their  $\gamma$  subunits. Compared with the ionotropic receptors, GPCRs mediate a slower response (on the order of seconds). Detailed depiction of the activation of G protein-coupled receptors is given in [Figure 2-2](#). Here we depict a receptor coupled to the G protein  $G_s$  (the *s* stands for stimulatory to the enzyme adenylyl cyclase [AC]). Activation of such a receptor produces activation of AC and increases in cyclic adenosine monophosphate (cAMP) levels. G protein-coupled pathways exhibit major amplification properties, and, for example, in model systems researchers have demonstrated a 10,000-fold amplification of the original signal. The effects of cAMP are mediated largely by activation of protein kinase A (PKA). One major downstream target of PKA is CREB (cAMP response element-binding protein), which may be important to the mechanism of action of antidepressants.

**(C) *Receptor tyrosine kinases***. These receptors are activated by neurotrophic factors and are able to bring about acute changes in synaptic function, as well as long-term effects on neuronal growth and survival. These receptors contain intrinsic tyrosine kinase activity. Binding of the ligand triggers receptor dimerization and transphosphorylation of tyrosine residues in its cytoplasmic domain, which then recruits cytoplasmic signaling and scaffolding proteins.

The recruitment of effector molecules generally occurs via interaction of proteins with modular binding domains SH2 and SH3 (named after homology to the src oncogenes–src homology domains); SH2 domains are a stretch of about 100 amino acids that allow high-affinity interactions with certain phosphotyrosine motifs. The ability of multiple effectors to interact with phosphotyrosines is undoubtedly one of the keys to the pleiotropic effects that neurotrophins can exert. Shown here is a tyrosine kinase receptor type B (TrkB), which upon activation produces effects on the Raf, MEK (mitogen-activated protein kinase/ERK), extracellular response kinase (ERK), and ribosomal S6 kinase (RSK) signaling pathway. Some major downstream effects of RSK are CREB and stimulation of factors that bind to the AP-1 site (c-Fos and c-Jun). **(D) Nuclear receptors.** These receptors are transcription factors that regulate the expression of target genes in response to steroid hormones and other ligands. Many hormones (including glucocorticoids, gonadal steroids, and thyroid hormones) are able to rapidly penetrate into the lipid bilayer membrane, because of their lipophilic composition, and thereby directly interact with these cytoplasmic receptors inside the cell. Upon activation by a hormone, the nuclear receptor–ligand complex translocates to the nucleus, where it binds to specific DNA sequences, referred to as *hormone responsive elements* (HREs), and regulates gene transcription. Nuclear receptors often interact with a variety of coregulators that promote transcriptional activation when recruited (coactivators) and those that attenuate promoter activity (corepressors). However, nongenomic effects of neuroactive steroids have also been documented, with the majority of evidence suggesting modulation of ionotropic receptors. This figure illustrates both the genomic and the nongenomic effects. ATF1=activation transcription factor 1; BDNF=brain-derived neurotrophic factor; CaMKII= $\text{Ca}^{2+}$ /calmodulin-dependent protein kinase II; CREM=cyclic adenosine 5'-monophosphate response element

modulator; D<sub>1</sub>=dopamine<sub>1</sub> receptor; D<sub>5</sub>=dopamine<sub>5</sub> receptor; ER=estrogen receptor; GR=glucocorticoid receptor; GRK=G protein-coupled receptor kinase; P=phosphorylation; PR=progesterone receptor.

## PLATE 5. (Figure 2-2) G protein-coupled receptors and G protein activation.

All G proteins are heterotrimers consisting of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits. The receptor shuttles between a low-affinity form that is not coupled to a G protein and a high-affinity form that is coupled to a G protein. **(A)** At rest, G proteins are largely in their inactive state, namely, as  $\alpha\beta\gamma$  heterotrimers, which have GDP (guanosine diphosphate) bound to the  $\alpha$  subunit. **(B)** When a receptor is activated by a neurotransmitter, it undergoes a conformational (shape) change, forming a transient state referred to as a *high-affinity ternary complex*, comprising the agonist, the receptor in a high-affinity state, and the G protein. A consequence of the receptor interaction with the G protein is that the GDP comes off the G protein  $\alpha$  subunit, leaving a very transient empty guanine nucleotide binding domain. **(C)** Guanine nucleotides (generally

GTP) quickly bind to this nucleotide binding domain; thus, one of the major consequences of active receptor-G protein interaction is to facilitate guanine nucleotide exchange—this is basically the “on switch” for the G protein cycle. **(D)** A family of GTPase-activating proteins for G protein-coupled receptors has been identified, and they are called regulators of G protein signaling (RGS) proteins. Since activating GTPase activity facilitates the “turn off” reaction, these RGS proteins are involved in dampening the signal. Binding of GTP to the  $\alpha$  subunit of G proteins results in subunit dissociation, whereby the  $\alpha$ -GTP dissociates from the  $\beta\gamma$  subunits. Although not covalently bound, the  $\beta$  and  $\gamma$  subunits remain tightly associated and generally function as dimers. The  $\alpha$ -GTP and  $\beta\gamma$  subunits are now able to activate multiple diverse effectors, thereby propagating the signal. While they are in their active states, the G protein subunits can activate multiple effector molecules in a “hit and run” manner; this results in major signal amplification (i.e., one active G protein subunit can activate multiple effector molecules). The activated G protein subunits also dissociate from the receptor, converting the receptor to a low-affinity conformation and facilitating the dissociation of the agonist from the receptor. The agonist can now activate another receptor, and this also results in signal amplification. Together, these processes have been estimated to produce a 10,000-fold amplification of the signal in certain models. **(E)** Interestingly, the  $\alpha$  subunit has intrinsic GTPase activity, which cleaves the third phosphate group from GTP (G-P-P-P) to GDP (G-P-P). Since  $\alpha$ -GDP is an inactive state, the GTPase activity serves as a built-in timing mechanism, and this is the “turn off” reaction. **(F)** The reassociation of  $\alpha$ -GDP with  $\beta\gamma$  is thermodynamically favored, and the reformation of the inactive heterotrimer ( $\alpha\beta\gamma$ ) completes the G protein cycle.

## PLATE 6. (Figure 2-3) The serotonergic system.

This figure depicts the location of the major serotonin (5-HT)-producing cells (raphe nuclei) innervating brain structures **(A)**, and various cellular regulatory processes involved in serotonergic neurotransmission **(B)**. 5-HT neurons project widely throughout the CNS and innervate virtually every part of the neuroaxis. L-Tryptophan, an amino acid actively transported into presynaptic 5-HT-containing terminals, is the precursor for 5-HT. It is converted to 5-hydroxytryptophan (5-HTP) by the rate-limiting enzyme tryptophan hydroxylase (TrpH). This enzyme is effectively inhibited by the drug *p*-chlorophenylalanine (PCPA). Aromatic amino acid decarboxylase (AADC) converts 5-HTP to 5-HT. Once released from the presynaptic terminal, 5-HT can interact with a variety (15 different types) of presynaptic and postsynaptic receptors. Presynaptic regulation of 5-HT neuron firing activity and release

occurs through somatodendritic 5-HT<sub>1A</sub> (not shown) and 5-HT<sub>1B,1D</sub> autoreceptors, respectively, located on nerve terminals. Sumatriptan is a 5-HT<sub>1B,1D</sub> receptor agonist. (The antimigraine effects of this agent are likely mediated by local activation of this receptor subtype on blood vessels, which results in their constriction.) Buspirone is a partial 5-HT<sub>1A</sub> receptor agonist that activates both pre- and postsynaptic receptors. Cisapride is a preferential 5-HT<sub>4</sub> receptor agonist that is used to treat irritable bowel syndrome as well as nausea associated with antidepressants. The binding of 5-HT to G protein receptors (G<sub>o</sub>, G<sub>i</sub>, etc.) that are coupled to adenylyl cyclase (AC) and phospholipase C-β (PLC-β) will result in the production of a cascade of second-messenger and cellular effects. Lysergic acid diethylamide (LSD) likely interacts with numerous 5-HT receptors to mediate its effects. Pharmacologically this ligand is often used as a 5-HT<sub>2</sub> receptor agonist in receptor-binding experiments. Ondansetron is a 5-HT<sub>3</sub> receptor antagonist that is marketed as an antiemetic agent for chemotherapy patients but is also given to counteract side effects produced by antidepressants in some patients. 5-HT has its action terminated in the synapse by rapidly being taken back into the presynaptic neuron through 5-HT transporters (5-HTTs). Once inside the neuron, it can either be repackaged into vesicles for reuse or undergo enzymatic catabolism. The selective 5-HT reuptake inhibitors (SSRIs) and older-generation tricyclic antidepressants (TCAs) are able to interfere/block the reuptake of 5-HT. 5-HT is then metabolized to 5-hydroxyindoleacetic acid (5-HIAA) by monoamine oxidase (MAO), located on the outer membrane of mitochondria or sequestered and stored in secretory vesicles by vesicular monoamine transporters (VMATs). Reserpine causes a depletion of 5-HT in vesicles by interfering with uptake and storage mechanisms (depressive-like symptoms have been reported with this agent). Tranylcypromine is an MAO inhibitor (MAOI) and an effective antidepressant. Fenfluramine (an anorectic agent) and 3,4-

methylenedioxymethamphetamine (MDMA; “Ecstasy”) are able to facilitate 5-HT release by altering 5-HTT function. cAMP=cyclic adenosine monophosphate; DAG=diacylglycerol; IP<sub>3</sub>=inositol-1,4,5-triphosphate.

## PLATE 7. (Figure 2-4) The dopaminergic system.

This figure depicts the dopaminergic projections throughout the brain **(A)** and various regulatory processes involved in dopaminergic neurotransmission **(B)**. The amino acid L-tyrosine is

actively transported into presynaptic dopamine (DA) nerve terminals, where it is ultimately converted into DA. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-dopa) by the enzyme tyrosine hydroxylase (TH).  $\alpha$ -Methyl-*p*-tyrosine (AMPT) is a competitive inhibitor of tyrosine hydroxylase and has been used to assess the impact of reduced catecholaminergic function in clinical studies. The production of DA requires that L-aromatic amino acid decarboxylase (AADC) act on L-dopa. Thus, the administration of L-dopa to patients with Parkinson's disease bypasses the rate-limiting step and is able to produce DA quite readily. DA has its action terminated in the synapse by rapidly being taken back into the presynaptic neuron through DA transporters (DATs). DA is then metabolized to dihydroxyphenylalanine (DOPAC) by intraneuronal monoamine oxidase (MAO; preferentially by the MAO-B subtype) located on the outer membrane of mitochondria, or is sequestered and stored in secretory vesicles by vesicular monoamine transporters (VMATs). Reserpine causes a depletion of DA in vesicles by interfering and irreversibly damaging uptake and storage mechanisms.  $\gamma$ -Hydroxybutyrate inhibits the release of DA by blocking impulse propagation in DA neurons. Pargyline inhibits MAO and may have efficacy in treating parkinsonian symptoms by augmenting DA levels through inhibition of DA catabolism. Other clinically used inhibitors of MAO are nonselective and thus likely elevate the levels of DA, norepinephrine, and serotonin. Once released from the presynaptic terminal (because of an action potential and calcium influx), DA can interact with five different G protein-coupled receptors (D<sub>1</sub>-D<sub>5</sub>), which belong to either the D<sub>1</sub> or D<sub>2</sub> receptor family. Presynaptic regulation of DA neuron firing activity and release occurs through somatodendritic (not shown) and nerve terminal D<sub>2</sub> autoreceptors, respectively. Pramipexole is a D<sub>2</sub>/D<sub>3</sub> receptor agonist and has been documented to have efficacy as an augmentation strategy in cases of treatment-resistant depression

and in the management of Parkinson's disease. The binding of DA to G protein receptors ( $G_o$ ,  $G_i$ , etc.) positively or negatively coupled to adenylyl cyclase (AC) results in the activation or inhibition of this enzyme, respectively, and the production of a cascade of second-messenger and cellular effects (see diagram). Apomorphine is a  $D_1/D_2$  receptor agonist that has been used clinically to aid in the treatment of Parkinson's disease. (SKF-82958 is a pharmacologically selective  $D_1$  receptor agonist.) SCH-23390 is a  $D_1/D_5$  receptor antagonist. There are likely physiological differences between  $D_1$  and  $D_5$  receptors, but the current unavailability of selective pharmacological agents has precluded an adequate differentiation thus far. Haloperidol is a  $D_2$  receptor antagonist, and clozapine is a nonspecific  $D_2/D_4$  receptor antagonist (both are effective antipsychotic agents). Once inside the neuron, DA can either be repackaged into vesicles for reuse or undergo enzymatic catabolism. Nomifensine is able to interfere/block the reuptake of DA. The antidepressant bupropion has affinity for the dopaminergic system, but it is not known whether this agent mediates its effects through DA or possibly by augmenting other monoamines. DA can be degraded to homovanillic acid (HVA) through the sequential action of catechol-*O*-methyltransferase (COMT) and MAO. Tropolone is an inhibitor of COMT. Evidence suggests that the COMT gene may be linked to schizophrenia ([Akil et al. 2003](#)). cAMP=cyclic adenosine monophosphate; DOPA=dihydroxyphenylalanine; MT=methoxytyramine;

## PLATE 8. (Figure 2-5) The noradrenergic system.

This figure depicts the noradrenergic projections throughout the brain **(A)** and the various regulatory processes involved in norepinephrine (NE) neurotransmission **(B)**. NE neurons innervate nearly all parts of the neuroaxis, with neurons in the locus coeruleus being responsible for most of the NE in the brain (90% of NE in the forebrain and 70% of total NE in the brain). The amino acid L-tyrosine is actively transported into presynaptic NE nerve terminals, where it is ultimately converted into NE. The rate-limiting step is conversion of L-tyrosine to L-dihydroxyphenylalanine (L-dopa) by the enzyme tyrosine hydroxylase (TH).  $\alpha$ -Methyl-*p*-tyrosine (AMPT) is a competitive inhibitor of tyrosine hydroxylase and has been used to assess the impact of reduced catecholaminergic function in clinical studies. Aromatic amino acid decarboxylase (AADC) converts L-dopa to dopamine (DA). L-dopa

then becomes decarboxylated by decarboxylase to form DA. DA is then taken up from the cytoplasm into vesicles, by vesicular monoamine transporters (VMATs), and hydroxylated by dopamine  $\beta$ -hydroxylase (DBH) in the presence of  $O_2$  and ascorbate to form NE. Normetanephrine (NM), which is formed by the action of catechol-*O*-methyltransferase (COMT) on NE, can be further metabolized by monoamine oxidase (MAO) and aldehyde reductase to 3-methoxy-4-hydroxyphenylglycol (MHPG). Reserpine causes a depletion of NE in vesicles by interfering with uptake and storage mechanisms (depressive-like symptoms have been reported with this hypertension). Once released from the presynaptic terminal, NE can interact with a variety of presynaptic and postsynaptic receptors. Presynaptic regulation of NE neuron firing activity and release occurs through somatodendritic (not shown) and nerve-terminal  $\alpha_2$  adrenoreceptors, respectively. Yohimbine potentiates NE neuronal firing and NE release by blocking these  $\alpha_2$  adrenoreceptors, thereby disinhibiting these neurons from a negative feedback influence. Conversely, clonidine attenuates NE neuron firing and release by activating these receptors. Idazoxan is a relatively selective  $\alpha_2$  adrenoreceptor antagonist primarily used for pharmacological purposes. The binding of NE to G protein receptors ( $G_o$ ,  $G_i$ , etc.) that are coupled to adenylyl cyclase (AC) and phospholipase C- $\beta$  (PLC- $\beta$ ) produces a cascade of second-messenger and cellular effects (see diagram and later sections of the text). NE has its action terminated in the synapse by rapidly being taken back into the presynaptic neuron via NE transporters (NETs). Once inside the neuron, it can either be repackaged into vesicles for reuse or undergo enzymatic degradation. The selective NE reuptake inhibitor and antidepressant reboxetine and older-generation tricyclic antidepressant desipramine are able to interfere/block the reuptake of NE. On the other hand, amphetamine is able to facilitate NE release by altering NET function. Green spheres represent DA neurotransmitters; blue

spheres represent NE neurotransmitters. cAMP=cyclic adenosine monophosphate;  
DAG=diacylglycerol;  
DOPA=dihydroxyphenylalanine; IP<sub>3</sub>=inositol-1,4,5-triphosphate;  
NA=nucleus accumbens.

## PLATE 9. (Figure 2-6) The cholinergic system.

This figure depicts the cholinergic pathways in the brain **(A)** and various regulatory processes involved in cholinergic neurotransmission **(B)**. Choline crosses the blood-brain barrier to

enter the brain and is actively transported into cholinergic presynaptic terminals by an active uptake mechanism (requiring adenosine triphosphate [ATP]). This neurotransmitter is produced by a single enzymatic reaction in which acetyl coenzyme A (AcCoA) donates its acetyl group to choline by means of the enzyme choline acetyltransferase (ChAT). AcCoA is primarily synthesized in the mitochondria of neurons. Upon its formation, acetylcholine (ACh) is sequestered into secretory vesicles by vesicle ACh transporters (VATs), where it is stored. Vesamicol effectively blocks the transport of ACh into vesicles. An agent such as  $\beta$ -bungarotoxin or AF6<sub>4</sub>A is capable of increasing synaptic concentration of ACh by acting as a releaser or a noncompetitive reuptake inhibitor, respectively. In turn, agents such as botulinum toxin are able to attenuate ACh release from nerve terminals. Once released from the presynaptic terminals, ACh can interact with a variety of presynaptic and postsynaptic receptors. In contrast to many other monoaminergic neurotransmitters, the ACh signal is terminated primarily by degradation by the enzyme acetylcholinesterase (AChE) rather than by reuptake. Interestingly, AChE is present on both presynaptic and postsynaptic membranes and can be inhibited by physostigmine (reversible) and soman (irreversible). Currently, AChE inhibitors such as donepezil and galantamine are the only classes of agents that are FDA approved for the treatment of Alzheimer's disease. ACh receptors are of two types: muscarinic (G protein-coupled) and nicotinic (ionotropic). Presynaptic regulation of ACh neuron firing activity and release occurs through somatodendritic (not shown) and nerve terminal M2 autoreceptors, respectively. The binding of ACh to G protein-coupled muscarinic receptors that are negatively coupled to adenylyl cyclase (AC) or coupled to phosphoinositol hydrolysis produces a cascade of second-messenger and cellular effects (see diagram). ACh also activates ionotropic nicotinic acetylcholine (nACh) receptors. ACh has its action terminated in the synapse through rapid degradation by AChE, which liberates free

choline to be taken back into the presynaptic neuron through choline transporters (CTs). Once inside the neuron, it can be reused for the synthesis of ACh, can be repackaged into vesicles for reuse, or undergoes enzymatic degradation. There are some relatively new agents that selectively antagonize the muscarinic receptors, such as CI-1017 for M<sub>1</sub>, methoctramine for M<sub>2</sub>, 4-DAMP for M<sub>3</sub>, PD-102807 for M<sub>4</sub>, and scopolamine (hardly a new agent) for M<sub>5</sub> (although it also has affinity for the M<sub>3</sub> receptor). Nicotine receptors (or nACh receptors) are activated by nicotine and the specific alpha(4)beta(2\*) agonist metanicotine. Mecamylamine is an ACh receptor antagonist. cAMP=cyclic adenosine monophosphate; DAG=diacylglycerol; IP<sub>3</sub>=inositol-1,4,5-triphosphate; PLC=phospholipase C.

### Glutamate receptor subtypes: new classification

Ionotropic			Metabotropic		
NMDA	AMPA	Kainate	Group I	Group II	Group III
GluN1	GluA1	GluK1	mGlu1 a-b-c-d	mGlu2	mGlu4 a-b
GluN2A-B-C-D	GluA2	GluK2	mGlu5 a-b	mGlu3	mGlu6
GluN3A-B	GluA3	GluK3			mGlu7 a-b
	GluA4	GluK4			mGlu8 a-b
		GluK5			

---

**PLATE 10.** (*Figure 2-7*) The glutamatergic system.

This figure depicts the various regulatory processes involved in glutamatergic neurotransmission. The biosynthetic pathway for glutamate involves synthesis from glucose and the transamination of  $\alpha$ -ketoglutarate; however, a small proportion of glutamate is formed more directly from glutamine by glutamine synthetase. The latter is actually synthesized in glia and, via an active process (requiring adenosine triphosphate [ATP]), is transported to neurons, where in the mitochondria glutaminase is able to convert this precursor to glutamate. Furthermore, in astrocytes glutamine can undergo oxidation to yield  $\alpha$ -ketoglutarate, which can also be transported to neurons and participate in glutamate synthesis. Glutamate is either metabolized or sequestered and stored in secretory vesicles by vesicle glutamate transporters (VGluTs). Glutamate can then be released by a calcium-dependent excitotoxic process. Once released from the presynaptic terminal, glutamate is able to bind to numerous excitatory amino acid (EAA) receptors, including both ionotropic (e.g., NMDA [*N*-methyl-D-aspartate]) and metabotropic (mGlu) receptors. Presynaptic regulation of glutamate release occurs through metabotropic glutamate receptors (mGlu2 and mGlu3), which subserve the function of autoreceptors; however, these receptors are also located on the postsynaptic element. Glutamate has its action terminated in the synapse by reuptake mechanisms utilizing distinct glutamate transporters that exist on not only presynaptic nerve terminals but also astrocytes; indeed, current data suggest that astrocytic glutamate uptake may be more important for clearing excess glutamate, raising the possibility that astrocytic loss (as has been documented in mood disorders) may contribute to deleterious glutamate signaling, but more so by astrocytes. It is now known that a number of important intracellular proteins are able to alter the function of glutamate receptors (see diagram). Also, growth factors such as glial-derived neurotrophic

factor (GDNF) and S100 $\beta$  secreted from glia have been demonstrated to exert a tremendous influence on glutamatergic neurons and synapse formation. Of note, serotonin<sub>1A</sub> (5-HT<sub>1A</sub>) receptors have been documented to be regulated by antidepressant agents; this receptor is also able to modulate the release of S100 $\beta$ . AKAP=A kinase anchoring protein; AMPA= $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid; CaMKII=Ca<sup>2+</sup>/calmodulin-dependent protein kinase II; ERK=extracellular response kinase; H-ras=Harvey rat sarcoma proto-oncogene; GKAP=guanylate kinase-associated protein; Glu=glutamate; Gly=glycine; GTg=glutamate transporter glial; GTn=glutamate transporter neuronal; Hsp70=heat shock protein 70; MEK=mitogen-activated protein kinase/ERK; mGluR=metabotropic glutamate receptor; MyoV=myosin V; NMDAR=NMDA receptor; nNOS=neuronal nitric oxide synthase; PKA=phosphokinase A; PKC=phosphokinase C; PP1, PP2A, PP2B=protein phosphatases; PSD-95=an abundant postsynaptic density (PSD) protein that forms a two-dimensional lattice immediately under the postsynaptic membrane; PTP1D=a protein tyrosine phosphatase; PYK2=protein tyrosine kinase 2; Rac1=Ras-related C3 botulinum toxin substrate 1; Raf=Raf-1 proto-oncogene, serine/threonine kinase; Rap2=related to AP2 domain protein; RSK=ribosomal S6 kinase; SHP2=src homology 2 (SH2) domain-containing tyrosine phosphatase; Src=SRC proto-oncogene, non-receptor tyrosine kinase; SynGAP=synaptic Ras-GTPase activating protein.

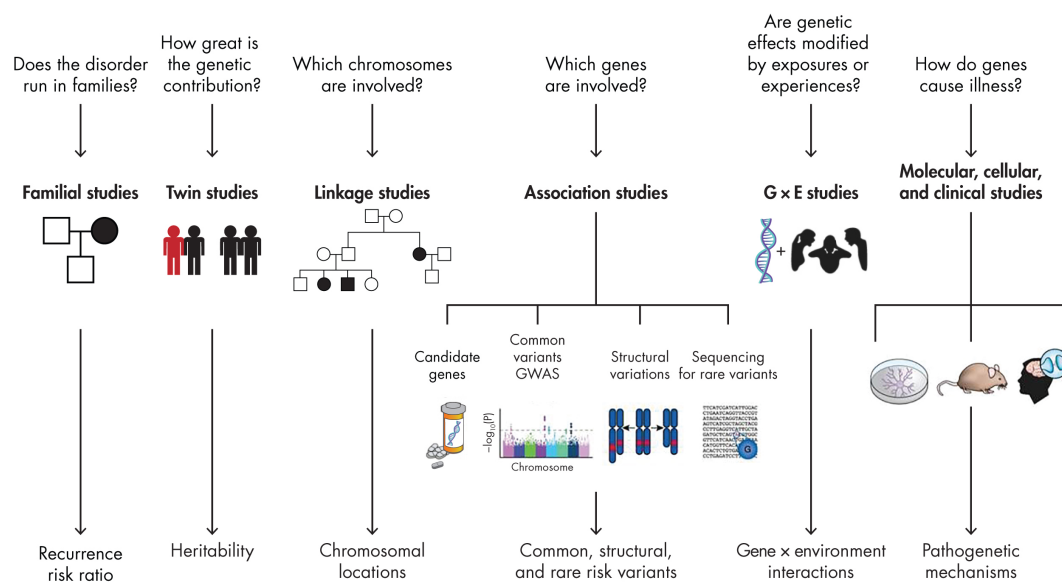

## PLATE 11. (Figure 2-8) The GABAergic system.

This figure depicts the various regulatory processes involved in GABAergic neurotransmission. The amino acid (and neurotransmitter) glutamate serves as the precursor for the biosynthesis of γ-aminobutyric acid (GABA). The rate-limiting enzyme for the process is glutamic acid decarboxylase (GAD), which utilizes pyridoxal phosphate as an important cofactor. Furthermore,

agents such as L-glutamine- $\gamma$ -hydrazide and allylglycine inhibit this enzyme and, thus, the production of GABA. Once released from the presynaptic terminal, GABA can interact with a variety of presynaptic and postsynaptic receptors. Presynaptic regulation of GABA neuron firing activity and release occurs through somatodendritic (not shown) and nerve-terminal GABA<sub>B</sub> receptors, respectively. Baclofen is a GABA<sub>B</sub> receptor agonist. The binding of GABA to ionotropic GABA<sub>A</sub> receptors and metabotropic GABA<sub>B</sub> receptors mediates the effects of this receptor. The GABA<sub>B</sub> receptors are thought to mediate their actions by being coupled to Ca<sup>2+</sup> or K<sup>+</sup> channels via second-messenger systems. Many agents are able to modulate GABA<sub>A</sub> receptor function. Benzodiazepines, such as diazepam, increase Cl<sup>-</sup> permeability, and there are numerous available antagonists directed against this site. There is also a distinctive barbiturate binding site on GABA<sub>A</sub> receptors, and many psychotropic agents are capable of influencing the function of this receptor (see blown-up diagram). GABA is taken back into presynaptic nerve endings by a high-affinity GABA uptake transporter (GABAT) similar to that of the monoamines. Once inside the neuron, GABA can be broken down by GABA transaminase (GABA-T), which is localized in the mitochondria; GABA that is not degraded is sequestered and stored in secretory vesicles by vesicular GABA transporters (VGATs), which differ from vesicular monoamine transporters (VMATs) in their bioenergetic dependence. The metabolic pathway that produces GABA, mostly from glucose, is referred to as the *GABA shunt*. The conversion of  $\alpha$ -ketoglutarate into glutamate by the action of GABA-T and GAD catalyzes the decarboxylation of glutamic acid to produce GABA. GABA can undergo numerous transformations, of which the simplest is the reduction of succinic semialdehyde (SS) to  $\gamma$ -hydroxybutyrate (GHB). On the other hand, when SS is oxidized by succinic semialdehyde dehydrogenase (SSADH), the production of succinic acid (SA) occurs. GHB has received attention because it regulates

narcoleptic episodes and may produce amnestic effects. The mood stabilizer and antiepileptic drug valproic acid is reported to inhibit SSADH and GABA-T. AC=adenylyl cyclase; TBPS=*t*-butylbicyclophosphorothionate.

# **Drugs for Treatment of Bipolar Disorder**

# CHAPTER 36

## Lithium

Masoud Kamali, M.D.

Venkatesh Basappa Krishnamurthy, M.D.

Raman Baweja, M.D.

Erika F.H. Saunders, M.D.

Alan J. Gelenberg, M.D.

---

## History and Discovery

---

After noting the sedating properties of lithium in animals, Cade first described the successful treatment of mania with lithium salts ([Cade 1949](#)). The U.S. Food and Drug Administration (FDA) approved lithium for the treatment of acute mania in 1970 and for the maintenance treatment of bipolar disorder 4 years later ([Jefferson and Greist 1977](#)). However, lithium did not enter the market easily in the United States. Pharmaceutical companies were reluctant to produce this inexpensive drug that they could not patent ([Kline 1973](#)). Lithium is a highly cost-effective treatment for

bipolar disorder ([Chisholm et al. 2005](#)). A growing number of medications with proven efficacy in bipolar disorder have become available since the introduction of lithium, including anticonvulsants and second-generation (atypical) antipsychotics. In contrast to many of these medications, lithium is available generically and is relatively affordable. These features, added to lithium's effectiveness, have given it longevity among the psychopharmacological treatment options for bipolar disorder.

---

## Structure-Activity Relations

---

Lithium is the lightest alkali metal and a monovalent cation, and it shares some properties with sodium, potassium, and calcium. It is the third element of the periodic table. Substitution of or competition with other cations may contribute to its effects ([Baldessarini 1996](#); [Ward et al. 1994](#)).

---

## Pharmacological Profile

---

Lithium is minimally protein bound, does not undergo biotransformation, and is renally eliminated ([Kilts 2000](#)). Its narrow therapeutic index necessitates careful drug monitoring. Lithium appears to affect multiple neurotransmitter systems (see "Neurotransmitter Effects" subsection under "Mechanisms of Action"), and it alters second-messenger systems such as cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) ([Ward et al. 1994](#)).

---

# Pharmacokinetics and Disposition

---

Lithium is available in multiple preparations, including lithium carbonate tablets and capsules, lithium citrate, and slow-release formulations ([Jefferson et al. 1983](#)). Lithium is absorbed from the gastrointestinal tract and is renally excreted unchanged within approximately 24 hours ([Baldessarini 1996](#); [Baldessarini and Tarazi 2001](#)). Peak plasma concentrations are reached within 1-2 hours with rapid-release preparations and within 4-5 hours with sustained-release formulations ([Finley et al. 1995](#)). Lithium is not protein bound and is evenly distributed in total body water space ([Jermain et al. 1991](#)). Lithium excretion is controlled by osmotic factors and is a function of renal sufficiency ([Birch et al. 1980](#)). Steady-state concentrations are achieved within 4-5 days ([Keck and McElroy 2002](#)).

---

## Mechanism of Action

---

Despite extensive research, the exact mechanism of lithium's action as a mood stabilizer has yet to be elucidated. Multiple theories, based on animal models and on limited studies in humans, have been proposed. In the following pages we review theories centering on lithium's effects on various neurotransmitter systems, on intracellular second-messenger systems, and on signal transduction, as well as a unifying theory focused on lithium's neuroprotective effects.

# Neurotransmitter Effects

Lithium brings about changes in several of the major neurotransmitter systems in the brain, with the overall effect being stimulation of inhibitory transmission and inhibition of excitatory signals ([Malhi et al. 2013](#)). Chronic administration of lithium in mice increases and stabilizes glutamate uptake. This modulatory action could, in part, explain lithium's antimanic effect because it results in overall reduction of an excitatory neurotransmitter ([Dixon and Hokin 1998](#)). Lithium also normalizes low cerebrospinal fluid (CSF) levels of  $\gamma$ -aminobutyric acid (an inhibitory neurotransmitter) in bipolar subjects (see [Berrettini et al. 1983, 1986](#); [Brambilla et al. 2003](#)).

Lithium enhances norepinephrine and serotonin function in the central nervous system, which could explain its antidepressant effects ([Price et al. 1990](#); [Schildkraut et al. 1969](#); [Stern et al. 1969](#)). Of particular interest is lithium's confirmed antagonistic action at serotonin 1A (5-HT<sub>1A</sub>) and serotonin 1B (5-HT<sub>1B</sub>) autoreceptors ([Haddjeri et al. 2000](#); [Massot et al. 1999](#)); such action would have the effect of increasing serotonin availability in the synaptic cleft ([Shaldubina et al. 2001](#)). Clinically, 5-HT<sub>1A</sub> receptors may be involved in alleviation of depression, and 5-HT<sub>1B</sub> receptors may play a role in the regulation of sleep, sensorimotor inhibition, and locomotor activity ([Monti et al. 1995](#); [Sipes and Geyer 1996](#)).

## Inositol Depletion

There has been much focus on the role of the inositol cycle in the clinical effects of lithium. Lithium is a noncompetitive

inhibitor of inositol monophosphatase, depleting free inositol within 5 days of treatment initiation ([Berridge et al. 1989](#)). These changes last for 3–4 weeks after lithium is discontinued ([Moore et al. 1999](#)). Depletion of free inositol can lead to effects on neurotransmitter and intracellular second-messenger systems linked to the inositol cycle. For example, adrenergic, serotonergic, and cholinergic receptor subtypes are coupled to the cycle via G proteins, and the cycle in turn regulates protein kinase C action, which appears to be influenced by lithium treatment in mania ([Hahn et al. 2005](#)).

Of note, depression is associated with low CSF levels of inositol in humans ([Barkai et al. 1978](#)). Exogenous inositol can alleviate depression ([Levine et al. 1993, 1995](#)) and panic attacks ([Benjamin et al. 1995](#)). [Belmaker et al. \(1996\)](#) suggested a complex “pendulum” relationship between inositol and lithium that may provide a basis for understanding lithium’s antimanic and antidepressant effects.

## Glycogen Synthase Kinase Inhibition

Glycogen synthase kinase 3 (GSK-3) is an enzyme with direct involvement in gene transcription, synaptic plasticity, and cell structure ([Malhi et al. 2013](#)). Both lithium ([Klein and Melton 1996](#); [Li et al. 2007](#)) and valproate inhibit GSK-3, suggesting that signaling pathways that converge in GSK-3 are important in bipolar disorder ([G. Chen et al. 1999](#)). GSK-3 is an inhibitor of the Wnt protein-signaling pathway, which affects neuronal signal transduction. Lithium thus would be predicted to mimic Wnt signaling ([Phiel and Klein 2001](#)). Wnt signaling triggers a cascade of

events that leads to stimulation of protein kinase C activity ([Grahame-Smith 1998](#); [Williams and Harwood 2000](#)). Thus, lithium's actions on both the inositol cycle and the GSK-3 signaling pathway lead to a common effect on protein kinase C. Because this enzyme's activity has been reported to be increased in bipolar disorder, protein kinase C inhibitors have been investigated for their potential treatment utility ([Zarate and Manji 2009](#)).

## Neurotrophic and Neuroprotective Effects

A unifying theory posits that lithium's mechanism of action may be related to its neurotrophic and neuroprotective effects ([Quiroz et al. 2010](#)). Patients treated with lithium have larger cortical and hippocampal volumes ([Hajek et al. 2012](#); [Moore et al. 2000](#)), and these effects are independent of treatment response ([Hajek et al. 2014](#)). One proposed mechanism is lithium's activation of the transcription factor cyclic adenosine monophosphate response element-binding protein (CREB), which in turn increases the expression of brain-derived neurotrophic factor and the antiapoptotic bcl-2 (b-cell lymphoma 2) proteins ([Alda 2015](#); [Quiroz et al. 2010](#)). Another proposed mechanism is inhibition of GSK-3 and subsequent activation of the Akt neuroprotective pathway ([Tajes et al. 2009](#)).

---

## Indications and Efficacy

---

# Bipolar Disorder

## Acute Mania

[Cade \(1949\)](#) first published data on the efficacy of lithium in mania more than 60 years ago. As we approach the end of the second decade of the twenty-first century, lithium remains one of the most efficacious treatments for bipolar disorder.

**Lithium versus placebo.** Lithium has been shown in studies to be more efficacious than placebo in the treatment of acute mania ([Bowden et al. 1994, 2005](#); [Fountoulakis et al. 2012](#); [Goodwin et al. 1969](#); [Keck et al. 2009](#); [Kushner et al. 2006](#); [Maggs 1963](#); [Poolsup et al. 2000](#); [Schou et al. 1954](#); [Smith et al. 2007](#); [Stokes et al. 1971](#); [Yildiz et al. 2011](#)). A review of response rates in randomized trials of medication treatment indicated that lithium was at least somewhat efficacious in the treatment of mania, with a response rate of 70% (87 of 124 patients) ([Keck et al. 2000](#)).

**Lithium versus antipsychotics.** Early studies with lithium established its antimanic efficacy relative to first-generation (typical) antipsychotics ([Garfinkel et al. 1980](#); [Johnson et al. 1968](#); [Poolsup et al. 2000](#); [Prien et al. 1972](#); [Segal et al. 1998](#); [Shopsin et al. 1975](#); [Spring et al. 1970](#); [Takahashi et al. 1975](#)). A study by [Prien et al. \(1972\)](#) comparing lithium against chlorpromazine found that although chlorpromazine was more effective in reducing manic symptoms in severely ill patients, lithium also reduced symptoms while causing fewer side effects. However, a later meta-analysis concluded that lithium was

more effective than chlorpromazine in acute mania ([Poolsup et al. 2000](#)). A review of studies by [Goodwin and Zis \(1979\)](#) found lithium to be efficacious in at least 70% of patients, as defined by remission or marked improvement. In a 3-week double-blind study of lithium, haloperidol, and their combination for acute mania, patients who received haloperidol or haloperidol plus lithium had more significant improvement compared with those who received lithium alone ([Garfinkel et al. 1980](#)). The combination of lithium and haloperidol was as well tolerated as haloperidol alone. [Segal et al. \(1998\)](#) reported that inpatients with acute mania responded equally well to lithium, haloperidol, and the second-generation agent risperidone.

Lithium has also been studied in comparison with second-generation antipsychotic medications ([Berk et al. 1999](#); [Bowden et al. 2005](#); [Fountoulakis et al. 2012](#); [Keck et al. 2009](#); [Kushner et al. 2006](#); [Li et al. 2007](#); [Niufan et al. 2008](#); [Poolsup et al. 2000](#); [Segal et al. 1998](#); [Smith et al. 2007](#); [Yildiz et al. 2011](#)). However, many of these trials were focused on assessing the efficacy of the antipsychotic in a noninferiority approach rather than on demonstrating significant differences between the medications. For example, in a direct comparison with lithium, olanzapine produced greater improvement in manic symptoms over 4 weeks, but it also produced more weight gain ([Niufan et al. 2008](#)). By and large, antipsychotics appear to work faster than lithium but carry higher risks for weight gain and other metabolic effects ([Fountoulakis et al. 2012](#); [Yildiz et al. 2011](#)).

In a recent study, the addition of lithium to therapy with extended-release quetiapine was found to be more efficacious than add-on placebo (i.e., quetiapine monotherapy) in patients with bipolar mania ([Bourin et al.](#)

2014). In a study in which patients with acute mania who had not adequately responded to lithium or divalproex were randomly assigned to receive adjunctive ziprasidone at two dosage ranges (20–40 mg/day or 60–80 mg/day) or placebo for 3 weeks in addition to their mood stabilizer (Sachs et al. 2012b), ziprasidone failed to show clinical or statistical separation from placebo. However, the high proportion of enrolled subjects that did not meet all eligibility criteria for the study may have contributed to the negative findings (Sachs et al. 2012a). In one study, adjunctive gabapentin added to lithium was found to be effective in treating acute mania (Astaneh and Rezaei 2012).

**Lithium versus anticonvulsants.** Double-blind randomized studies suggest that carbamazepine and lithium are equally effective in the treatment of acute mania (Fountoulakis et al. 2012; Lerer et al. 1987; Okuma et al. 1990; Poolsup et al. 2000; Small et al. 1991; Yildiz et al. 2011). In a direct comparison of lithium and divalproex, Bowden et al. (1994) demonstrated a similar advantage for both agents over placebo, with lithium and divalproex each achieving response in about 48% of patients over 3 weeks. A 12-week study of patients randomly assigned to open treatment with lithium or divalproex yielded additional evidence of the two agents' comparable efficacy and tolerability over a longer-than-usual study period (Bowden et al. 2008, 2010). A meta-analysis of available randomized controlled trials likewise showed that lithium and valproate were equally effective in acute mania (Poolsup et al. 2000). In a meta-analysis examining the efficacy of lithium, valproate, and carbamazepine in mania, no significant differences in efficacy were found among the three agents (Emilien et al. 1996). However, only some of the included

studies were placebo controlled. Anticonvulsants were generally better tolerated than lithium. The presence of neurological abnormalities may predict a better response to anticonvulsants than to lithium in mania. One study found that patients with electroencephalogram abnormalities are more likely to respond to valproate than to lithium ([Reeves et al. 2001](#)).

Mixed mania—the co-occurrence of mania with depression—may predict a poorer response to lithium. [Freeman et al. \(1992\)](#), in a direct comparison of lithium and valproate, showed that a favorable response to valproate was associated with high pretreatment depressive symptom scores ([Fountoulakis et al. 2012](#)). To further investigate the relation between co-occurring depressive symptoms and treatment response in acute mania, [Swann et al. \(1997\)](#) designed a parallel-group study of lithium versus divalproex and analyzed outcomes relative to the presence of a mixed affective state. They found that the presence of depressive symptoms during an acute manic episode was associated with a poorer response to lithium and a better response to divalproex. Lithium plus topiramate showed no superiority to lithium plus placebo in acute mania ([Mirsepassi et al. 2013](#)).

## **Psychotic Mania**

Lithium is equally effective in psychotic and nonpsychotic mania, and early improvement in psychotic symptoms was found to predict higher remission and response rates ([de Sousa et al. 2012](#)).

## **Bipolar Depression**

Lithium is considered a first-line treatment for acute bipolar depression ([Compton and Nemeroff 2000](#)). [Goodwin and Jamison \(1990\)](#) analyzed placebo-controlled trials in bipolar depression and found that 79% of bipolar patients had either a complete or a partial response to lithium. Placebo-controlled trials showing the efficacy of lithium in bipolar depression include those by [Baron et al. \(1975\)](#), [Donnelly et al. \(1978\)](#), [Fieve et al. \(1968\)](#), [Goodwin et al. \(1969, 1972\)](#), [Greenspan et al. \(1970\)](#), [Mendels \(1975\)](#), and [Noyes et al. \(1974\)](#). These studies generally were small (involving between 3 and 40 patients [[Goodwin et al. 1972](#)]).

A recent meta-analytic summary of the above-listed short studies showed a significant advantage for lithium over placebo in bipolar disorder versus unipolar depression ([Selle et al. 2014](#)). In a study in which 802 patients were randomly assigned to 8 weeks of treatment with lithium (600–1,800 mg/day), quetiapine (300 mg/day or 600 mg/day), or placebo ([Young et al. 2010](#)), lithium failed to separate significantly from placebo on the main efficacy measure (Montgomery-Åsberg Depression Rating Scale [MADRS] score); however, the study was powered to show an effect for quetiapine, and the mean serum level in lithium-treated subjects was low (0.6 mmol/L).

In the Bipolar CHOICE (Clinical Health Outcomes Initiative in Comparative Effectiveness) trial, 482 patients with bipolar I or II disorder, the majority (>88%) of whom were experiencing depressive symptoms at study entry ([Nierenberg et al. 2016](#)), were randomly assigned to receive lithium plus adjunctive personalized treatment (APT,  $n=240$ ) or quetiapine plus APT ( $n=242$ ) for 6 months. In this study, which used new clinical trials methodology, participants in the lithium group were not given a second-generation antipsychotic, and those in the quetiapine group

were not given lithium; however, other adjunctive treatments were provided in accordance with best-practice guidelines ([Nierenberg et al. 2013](#)). Both groups showed improvement, with 20% achieving sustained response over the study period, and no differences in outcome were detected between the lithium and quetiapine groups ([Nierenberg et al. 2013](#)).

In the **L**ithium Treatment **M**oderate-dose **U**se **S**tudy (LiTMUS) study ([Nierenberg et al. 2013](#)), 283 bipolar I and II patients were randomly assigned to receive optimized personalized treatment (OPT; evidence-based, guideline-informed care) alone or OPT plus lithium at a moderate dosage. The lithium dosage was fixed at 600 mg/day for the first 2 months of the study but was allowed to change based on clinical need after that. Over the 6 months of the trial, the two groups had similar scores on clinical outcome measures, with a sustained remission rate of 27%. Although the addition of lithium conferred no advantage over OPT alone, fewer patients in the lithium-plus-OPT group than in the OPT-only group received second-generation antipsychotics.

In 2004, an expert consensus report recommended lithium as monotherapy for mild to moderate depression in bipolar I disorder and as a component of an initial medication regimen in severe nonpsychotic and psychotic depression ([Keck et al. 2004](#)).

## **Rapid Cycling**

In 1974, [Dunner and Fieve](#) observed that bipolar patients who had not responded to long-term lithium prophylaxis were more likely to have had four or more mood episodes per year, giving rise to the belief that lithium is not effective in treating rapid cycling. However, subsequent studies have

shown that rapid-cycling bipolar disorder responds poorly to most available treatments and that treatment with lithium does improve the burden of illness. In a study examining lithium's efficacy in rapid-cycling bipolar disorder, [Dunner et al. \(1977\)](#) found that patients who had received lithium for at least 1 year had a higher percentage of "well time" relative to baseline and reported that their mood episodes were shorter and less severe. In an analysis of retrospective and prospective data from 51 patients with rapid-cycling bipolar disorder, [Wehr et al. \(1988\)](#) showed that even among patients with continuous rapid cycling, the manic phases were abbreviated and attenuated. A long-term prospective study of open-label treatment with lithium found a higher rate of recurrence among rapid cyclers versus non-rapid cyclers but similar improvement in symptoms and morbidity (as measured by percentage of time ill, episode frequency, and time to recurrence) ([Baldessarini et al. 2000](#)). Finally, a meta-analysis of clinical studies comparing subjects with rapid-cycling and non-rapid-cycling bipolar disorder showed that although lithium was less effective in preventing recurrence among rapid cyclers, it did have beneficial effects on severity and duration of episodes ([Kupka et al. 2003](#)). In a 20-month double-blind, parallel-group comparison study, [Calabrese et al. \(2005\)](#) evaluated lithium versus divalproex monotherapy for maintenance treatment in rapid-cycling patients who had been stabilized on a combination of lithium and divalproex. The rates of relapse were similar for lithium-treated and divalproex-treated patients.

## **Prophylaxis and Maintenance**

Prophylactic or maintenance therapy is often considered after resolution of an acute mood episode. Lithium is the

best-studied drug for this indication. [Tondo et al. \(1998\)](#) found lithium to be effective in long-term use (>1 year) in decreasing frequency of mood episodes and “time ill” in patients with bipolar I or bipolar II disorder. Benefits of lithium treatment were not significantly different among patients with psychotic or mixed episodes, rapid cycling, or more classic forms. There was no decrease in efficacy with long-term use. Despite finding evidence for lithium’s efficacy, [Kulhara et al. \(1999\)](#) noted that only 24% of the patients followed in a lithium clinic were free of mood episodes while receiving lithium prophylaxis (average duration of monitoring: 11 years). Treatment nonadherence and/or subtherapeutic lithium serum levels (<0.4 mEq/L), high numbers of psychosocial stressors, higher numbers of depressive episodes before lithium treatment, and poor social support predicted poorer response to lithium prophylaxis. In contrast, starting lithium early in the course of illness predicted a better response to treatment ( $P<0.001$ ), after episode polarity, sex, age at onset, duration of illness, and duration of lithium prophylaxis were accounted for ([Franchini et al. 1999](#)).

In a comparison of lithium, divalproex, and placebo in a 1-year treatment study of patients with bipolar I disorder who had recently recovered from an index manic episode, [Bowden et al. \(2000\)](#) found that median times to 50% survival without any mood episode were 40 weeks for divalproex, 24 weeks for lithium, and 28 weeks for placebo, although the differences were not statistically significant. Patients who received divalproex remained in treatment significantly longer than did those who received lithium.

In a study comparing the prophylactic efficacy of lithium versus placebo, [Prien et al. \(1973\)](#) found that lithium was more effective than placebo in preventing relapses

requiring hospitalization. [Bowden et al. \(2003\)](#) compared the efficacy of lamotrigine, lithium, and placebo in preventing relapse to mood episodes among bipolar I subjects with a recent manic or hypomanic episode. After completing a stabilization phase during which treatment with lamotrigine was initiated and other medications were discontinued, subjects were randomly assigned to one of the three drug groups and followed for 18 months. Both lithium and lamotrigine were superior to placebo in prolonging the time to any mood episode, with lithium predominantly effective against manic, hypomanic, or mixed episodes and lamotrigine predominantly effective against depressive episodes. A similar study in bipolar I subjects with a recent depressive episode ([Calabrese et al. 2003](#)) reported the same findings. A post hoc analysis of the two studies revealed that lithium not only delayed the time between random assignment and onset of subsyndromal symptoms but also delayed the time between onset of subsyndromal symptoms and emergence of the full mood episode ([Frye et al. 2006](#)). In a study by [Weisler et al. \(2011\)](#), bipolar subjects who had been stabilized on quetiapine were randomly assigned to continue quetiapine or be switched to lithium or placebo for up to 104 weeks. Both lithium and quetiapine were superior to placebo in prevention of manic or depressive episodes. In a meta-analysis of 19 randomized controlled blinded trials, [Davis et al. \(1999\)](#) found lithium to be more efficacious than placebo in preventing relapse. In a meta-analysis by [Geddes et al. \(2004\)](#) involving 770 participants, lithium was found to be more effective than placebo in preventing all relapses and manic relapses, but its efficacy in preventing depressive relapses was less robust. In another systematic review and meta-analysis of randomized and quasi-randomized

controlled trials, lithium, compared with placebo, was effective in the prevention of relapse in bipolar disorder, especially manic episodes ([Beynon et al. 2009](#)). [Popovic et al. \(2012\)](#) used a new metric—the polarity index (number needed to treat [NNT] for prevention of depression divided by NNT for prevention of mania)—to define the profiles of drugs used in the maintenance treatment of bipolar disorder. A polarity index of 1.39 was calculated for lithium, a value indicating its relatively greater antimanic versus antidepressant prophylactic efficacy.

The Bipolar Affective Disorder: Lithium/Anticonvulsant Evaluation (BALANCE) study examined the effects of lithium monotherapy, valproate monotherapy, or lithium-plus-valproate combination therapy for relapse prevention in a large international cohort ([BALANCE Investigators and Collaborators et al. 2010](#)). More than 300 patients with bipolar I disorder initially completed a “run-in” phase during which they took both lithium and valproate. Of those who tolerated the combination, a subsequent randomization phase assigned subjects to lithium alone, valproate alone, or continued combination treatment for up to 2 years of follow-up. The primary outcome measure was time to new intervention (either medication change or hospitalization) for an emerging mood episode. The study results showed that the combination of lithium and valproate was superior to valproate alone and also suggested that lithium monotherapy was superior to valproate monotherapy. The apparent discrepancy between the latter finding and the conclusions of [Bowden et al. \(2010\)](#) described above may reflect differences in the population studied and in the outcome measures used; alternatively, the valproate dosage in the BALANCE study may have been suboptimal for preventing acute mania.

In a double-blind, randomized maintenance trial of lithium versus olanzapine, bipolar patients experiencing mixed or manic symptoms first received open-label co-treatment with lithium and olanzapine ([Tohen et al. 2005](#)). Those whose symptoms remitted were then randomly assigned to monotherapy with either lithium or olanzapine for 52 weeks. Recurrence rates were similar for the two groups, with 38.8% of patients on lithium and 30.0% of those on olanzapine experiencing a relapse. Whereas the two drugs were comparable in prevention of depressive episodes, olanzapine was more effective than lithium in prevention of manic and mixed episodes.

**Maintenance dosing.** Once-daily dosing of lithium at bedtime yields higher brain-to-serum ratios of lithium levels compared with twice-daily dosing schedules ([Soares et al. 2001](#)). Investigators have observed substantial variations in brain lithium levels among people with similar serum lithium levels ([González et al. 1993](#)). In a study evaluating maintenance treatment with lithium at dosages yielding low (0.4–0.6 mmol/L) versus standard (0.8–1.0 mmol/L) serum levels, [Gelenberg et al. \(1989\)](#) found that the risk of relapse was 2.6 times higher in patients randomly assigned to maintenance lithium at the low serum level. However, in a reanalysis of the data ([Perlis et al. 2002](#)), the higher relapse rate observed with the low serum level was found to be associated with the abrupt reduction in lithium dosage that occurred following randomization in patients who were switched from the standard range to the low range. Thus, an abrupt reduction in lithium dosage may negatively impact the course of illness.

[Nolen and Weisler \(2013\)](#) conducted a post hoc analysis of a double-blind trial in patients with bipolar disorder who

were stabilized on quetiapine after a manic, depressive, or mixed episode and then randomly assigned to continue quetiapine or be switched to lithium or placebo for up to 104 weeks. Times to recurrence of any mood episode, as well as to recurrence of a manic or a depressive episode, were longer for patients with serum lithium levels of 0.6–1.2 mEq/L than for patients with serum lithium levels less than 0.6 mEq/L. No difference in time to recurrence was found between patients receiving placebo and patients with lithium levels lower than 0.6 mEq/L, providing evidence that maintenance lithium dosages should be high enough to achieve plasma levels of at least 0.6 mEq/L for prevention of mania and depressive episodes in bipolar disorder. One limitation of this study was that subjects were not randomly assigned to the lithium dosing groups. In a similar post hoc analysis by [Severus et al. \(2010\)](#), subjects were first stabilized on a combination of lithium and olanzapine and then randomly assigned to lithium (at dosages aimed at achieving low [0.6 mmol/L], medium [0.6–0.79 mmol/L], or high [ $>0.8$  mmol/L] serum levels) or olanzapine (10 mg/day or 10–20 mg/day) for the maintenance phase. The low-serum-level lithium group had a significantly higher risk of relapse to manic or mixed—but not to depressive—episodes compared with the medium- and the high-lithium-level groups and had an increased risk of depression compared with the high-dosage olanzapine group. These findings provide further evidence that lithium levels should be higher than 0.6 mmol/L for optimal protection against relapse to manic, mixed, or depressive episodes.

# Unipolar Depression (Major Depressive Disorder)

An analysis of five controlled trials of lithium augmentation of antidepressant treatment in patients with unipolar depression found significant improvement in 56%–96% of patients ([Austin et al. 1991](#); [Carvalho et al. 2009](#); [Heit and Nemeroff 1998](#); [Heninger et al. 1983](#); [Kantor et al. 1986](#); [Schöpf et al. 1989](#); [Stein and Bernadt 1993](#); [Zusky et al. 1988](#)). Two separate meta-analyses of randomized, double-blind, placebo-controlled trials in unipolar and bipolar depression evaluated lithium's efficacy in augmenting and accelerating clinical response to antidepressant treatment ([Crossley and Bauer 2007](#)). Although there was firm evidence of lithium's efficacy as an augmentation agent, there was only modest evidence of its efficacy in accelerating response to antidepressants. In a naturalistic study by [Köhler et al. \(2013\)](#), patients with unipolar depression who had not responded to the first antidepressant they received were 1) started on adjunctive lithium, 2) started on a second-generation antipsychotic (SGA), 3) switched to a different antidepressant, or 4) given a combination of two antidepressants. Patients who received lithium or SGA augmentation showed greater improvement compared with patients switched to another antidepressant or an antidepressant combination. This study was limited by lack of randomization and failure to define nonresponse.

In treatment-refractory depression, open-label data support the addition of lithium to antidepressants, including tricyclic antidepressants (TCAs), trazodone, and selective serotonin reuptake inhibitors (SSRIs) ([Bschor et al. 2001](#);

de Montigny et al. 1981, 1983, 1985; Dinan 1993; Fontaine et al. 1991; Price et al. 1986). Double-blind and open-label studies support the use of lithium for augmentation of TCAs, monoamine oxidase inhibitors (MAOIs), trazodone, mirtazapine, and SSRIs (Baumann et al. 1996; Fava et al. 1994; Heninger et al. 1983; Joffe et al. 1993; Kantor et al. 1986; Katona et al. 1995; Nierenberg et al. 2006; Schöpf et al. 1989; Schüle et al. 2009; Zusky et al. 1988). In the large Sequenced Treatment Alternatives to Relieve Depression (STAR\*D) multisite trial, 15.9% of subjects who did not experience remission with citalopram monotherapy and another medication trial achieved remission after the addition of lithium (Nierenberg et al. 2006). Single studies have found that severe depression (Bschor et al. 2013), weight loss and psychomotor retardation (Alvarez et al. 1997), more than three lifetime major depressive episodes, and a family history of major depressive or bipolar disorder in a first-degree relative (Sugawara et al. 2010) may predict a good response to lithium augmentation in treatment-resistant depression. These studies are limited by small heterogeneous samples, variations in treatment duration, use of mostly nonblinded, retrospective study designs, and absence of a placebo comparator.

Timing of onset of lithium action when the drug is used as an adjunct to antidepressant treatment remains unclear. A meta-analysis of placebo-controlled trials of lithium augmentation in treatment-resistant depression found that a minimum lithium dosage of 800 mg/day (or dosing to produce a serum level of  $\geq 0.5$  mEq/L) and a treatment duration of at least 2 weeks favored lithium augmentation as compared with placebo (Bauer et al. 1999).

# Suicide: Is Lithium Protective?

Up to 50% of bipolar patients attempt suicide ([Compton and Nemeroff 2000](#)). In an analysis of studies of lithium treatment ([Schou 1998](#)), bipolar patients treated with lithium had a lower overall mortality rate than bipolar patients in general and did not have a significantly higher suicide rate than the general population. [Tondo et al. \(1997\)](#) reviewed studies of the use of lithium in the treatment of major mood disorders; these included 28 studies that involved more than 17,000 patients. Risks of completed and attempted suicides were 8.6-fold higher in patients who were not given lithium compared with those who were. A recent review by [Lewitzka et al. \(2015\)](#) confirmed the antisuicidal effects of lithium. In meta-analyses of studies of lithium treatment in major mood disorders, [Tondo et al. \(2001\)](#), [Baldessarini et al. \(2006\)](#), [Guzzetta et al. \(2007\)](#), and [Cipriani et al. \(2013\)](#) found significantly lower suicide risk for subjects who were receiving treatment with lithium. Methodological problems exist in the studies that have examined lithium and suicide risk, and large-scale prospective studies are needed to inform treatment decisions ([Gelenberg 2001](#)). In the first randomized, placebo-controlled trial investigating the effect of adjunctive lithium treatment in prevention of suicidal behavior, which was conducted by [Lauterbach et al. \(2008\)](#), survival analysis showed no significant difference in suicidal acts between lithium- and placebo-treated groups. However, post hoc analysis showed that all completed suicides occurred in the placebo group, suggesting that lithium may be effective in reducing the risk of completed suicide.

In a retrospective cohort population-based study of subjects enrolled in two large integrated health plans with a diagnosis of bipolar disorder who were treated with lithium or divalproex, [Goodwin et al. \(2003\)](#) found that the risks of suicide attempt and suicide death were lower during treatment with lithium than during treatment with divalproex. In a national registry-based follow-up study in Finland exploring the association between medication use and hospitalizations due to a suicide attempt, suicide death, and overall mortality with different psychotropic agents in bipolar disorder, [Toffol et al. \(2015\)](#) found that lithium was associated with a lower risk of suicide attempts as well as decreased suicide and all-cause mortality. In an intriguing systematic review of the association between mortality rates from suicide and the levels of lithium in drinking water, [Vita et al. \(2015\)](#) reported that higher lithium levels in drinking water are associated with reduced suicide risk in the general population.

---

## Use in Special Populations

---

### Children and Adolescents

Lithium is FDA approved for the treatment of bipolar disorder in adolescents and has been shown to be significantly more efficacious than placebo for both bipolar disorder and substance abuse, but not for major depressive disorder ([Findling et al. 2015](#); [Geller et al. 1998a, 1998b](#); [Ryan et al. 1999](#)). Lithium had a large effect size in the open-label treatment of acute manic or mixed episodes in children and adolescents ([Kowatch et al. 2000](#)) and of acute

depressive episodes in adolescents with bipolar I disorder ([Patel et al. 2006](#)), and it had a medium effect size in the randomized, placebo-controlled treatment of acute manic or mixed episodes in children and adolescents with bipolar I disorder ([Findling et al. 2015](#)). In a randomized, double-blind maintenance trial of lithium versus divalproex in children and adolescents ages 5–17 years ([Findling et al. 2005](#)), lithium-treated patients and divalproex-treated patients did not differ in time to relapse. However, in the Treatment of Early Age Mania (TEAM) study, risperidone was more effective than lithium or divalproex in children ages 6–15 years, whereas there was no difference in efficacy between lithium and divalproex. The incidence of metabolic side effects was higher with risperidone than with lithium, but the discontinuation rate was higher with lithium than with risperidone ([Geller et al. 2012](#)). An earlier study examining predictors of side effects associated with lithium administration in children found that when weight and serum lithium levels were controlled, younger age was associated with more side effects ([Campbell et al. 1991](#)).

## The Elderly

Lithium has shown effectiveness in elderly patients. In a retrospective trial, significantly more patients age 55 years or older improved with lithium than with valproate, especially in cases of classic mania, whereas the two drugs showed similar response rates when the analysis considered only the cases of mixed mania ([S.T. Chen et al. 1999](#)). The lithium serum-level range associated with improvement in elderly patients was similar to the therapeutic range in younger adults:  $\geq 0.8$  mmol/L.

Medical comorbidity may be a particular consideration in elderly patients. Volume depletion, use of nonsteroidal anti-inflammatory drugs, or use of thiazide diuretics can increase lithium levels ([Stoudemire et al. 1990](#)). The lithium dosage required to achieve therapeutic serum concentrations decreases threefold from middle to old age, with this trend continuing into the ninth and tenth decades of life ([Rej et al. 2014b](#)). In a population-based retrospective cohort study involving 1,388 bipolar patients ages 66 years and older, medical hospitalizations, 1-year acute medical health utilization outcomes, and medical comorbidity rates were not different among lithium users as compared with valproate users or nonlithium/nonvalproate users during 1-year follow-up ([Rej et al. 2015](#)).

Meta-analyses show that lithium is associated with increased risk of reduced urinary concentrating ability, but there is little evidence for a clinically significant reduction in renal function in most patients, and the risk of end-stage renal failure is low ([McKnight et al. 2012](#)). Lithium use is associated with an increased risk of renal failure among the older (ages 50 years and above) age group ([Close et al. 2014](#); [Rej et al. 2014a](#)). However, chronic lithium use at lower dosages did not affect renal function in elderly patients with mild cognitive impairment and dementia over a 4-year study period ([Aprahamian et al. 2014](#)). Because lithium is cleared almost exclusively by the kidneys, patients with end-stage renal disease receiving hemodialysis cannot eliminate lithium other than through dialysis. Lithium should be given only after a dialysis treatment and need not be given daily ([Stoudemire et al. 1990](#)).

Because lithium appears to have neuroprotective effects that may reduce oxidative damage, its potential role in prevention of neurocognitive decline in aging and

prevention of Alzheimer's disease has been suggested ([Bachmann et al. 2005](#); [Chen et al. 2000](#); [Cui et al. 2007](#); [Engel et al. 2006](#); [Mohammadianinejad et al. 2014](#); [Phiel et al. 2003](#); [Shao et al. 2005](#); [Su et al. 2004](#); [Tsaltas et al. 2007](#); [Yoshida et al. 2006](#)). A Danish study that followed more than 4,800 patients with newly diagnosed bipolar disorder over 10 years found that long-term treatment with lithium, but not with other psychopharmacological agents, was associated with a reduced risk of developing dementia ([Kessing et al. 2010](#)). A study that analyzed data from a national health insurance database in Taiwan concluded that lithium use was significantly related to a reduced risk of stroke in patients with bipolar disorder. The association between lithium use and reduced stroke risk was strongest for patients who received the highest lithium dosages, experienced the longest durations of lithium treatment, and had the highest rates of lithium exposure ([Lan et al. 2015](#)).

## Pregnant or Lactating Women and Their Children

The risks and benefits of lithium treatment must be carefully assessed in the context of pregnancy and breast feeding. Undertreated or untreated women with bipolar disorder are at increased risk for perinatal complications and poor pregnancy outcomes ([Jablensky et al. 2005](#); [Lee and Lin 2010](#)). A prospective observational study by [Diav-Citrin et al. \(2014\)](#) that compared lithium-exposed pregnancies with disease-matched and nonteratogenic-exposed control pregnancies found higher rates of miscarriage and preterm delivery in the lithium-exposed group compared with the nonteratogenic exposure group,

but no difference in rates of stillbirth or ectopic pregnancy. Data suggest that lithium exposure during pregnancy is less harmful than experts believed in past decades ([Cohen et al. 1994](#)). In fact, although the overall risk of Ebstein's anomaly—a rare cardiac malformation with an incidence of 1 in 20,000 live births—may be higher with lithium use (relative risk of 10–20 vs. the general population) than without, the prevalence associated with first-trimester lithium exposure is 0.05%–0.1% ([Cohen and Rosenbaum 1998](#)). In the observational study by [Diav-Citrin et al. \(2014\)](#), rates of major congenital anomalies after exclusion of genetic or cytogenetic anomalies were not significantly different in the lithium-exposed group compared with the bipolar patients not exposed to lithium and the nonteratogenic exposure group ([Diav-Citrin et al. 2014](#)). Cardiovascular anomalies occurred more frequently in the lithium-exposed group compared with the nonteratogenic exposure group, but after exclusion of anomalies that spontaneously resolved, there were no differences between the groups, and there was also no difference between groups in the rates of noncardiovascular anomalies ([Diav-Citrin et al. 2014](#)). The risk of cardiovascular anomalies with lithium is substantially lower than the risk of neural tube defects associated with some anticonvulsants used for mood stabilization. Overall, lithium is not a high-risk teratogen.

Lithium freely crosses the placenta. Lithium-exposed neonates are more likely than nonexposed neonates to be born preterm, to have lower birthweights, and to have longer hospital stays ([Newport et al. 2005](#)). Because birth complications are directly correlated with placental lithium concentrations, brief suspension (24–48 hours) of lithium

therapy before delivery has been suggested ([Newport et al. 2005](#)).

Although lithium is today considered a first-line treatment for bipolar disorder during pregnancy ([Larsen et al. 2015](#)), many women wish to discontinue all psychotropic medications or to discontinue lithium ([McCrea et al. 2015](#)) during pregnancy. In a longitudinal study of 89 women with bipolar disorder who continued or discontinued mood stabilizer treatment during pregnancy, [Viguera et al. \(2007b\)](#) reported an overall risk of recurrence of 71%. Risk of recurrence was twofold greater in women who discontinued mood stabilizer treatment compared with those who did not, and time to recurrence was 11 times shorter if the mood stabilizer was discontinued abruptly instead of gradually. Risk of recurrence was 1.6 times higher in women using a mood stabilizer other than lithium ([Viguera et al. 2007b](#)). In an earlier study of relapse after lithium discontinuation in pregnant and nonpregnant women with bipolar disorder, [Viguera et al. \(2000\)](#) found that rates of relapse were initially similar in the two groups but increased sharply during the postpartum period (70% vs. 24% in nonpregnant patients matched for time after discontinuation) ([Viguera et al. 2000](#)). This high risk of recurrence has prompted experts in the field to recommend postpartum prophylactic treatment with a mood stabilizer for women with bipolar disorder ([Cohen et al. 1995](#)).

Lithium is secreted in breast milk and is passed on to the infant. For this reason, and also because of a small number of case reports of adverse effects in nursing infants of mothers taking lithium, the American Academy of Pediatrics (AAP) had previously considered lithium use to be contraindicated in breast-feeding women ([Chaudron and Jefferson 2000](#)). However, that recommendation was

revised in 2001 to the recommendation that lithium be used with caution in breast feeding due to reports of adverse events ([American Academy of Pediatrics Committee on Drugs 2001](#)). The Committee on Drugs of the AAP now reports that lithium is present at clinically significant levels (10% or more of therapeutic maternal plasma concentration) in human milk. The AAP currently recommends that in addition to receiving counseling about the benefits of breast feeding, parents be informed of the potential risks for infants exposed to clinically significant levels and cautioned that the long-term effects of this exposure are unknown ([Sachs and Committee on Drugs 2013](#)). In a study of 10 mother-infant pairs, serum lithium levels in the infants ranged from 0.09 to 0.3 mEq/L (mean 0.16 mEq/L). Transient elevations in infant thyroid-stimulating hormone, blood urea nitrogen, and creatinine levels were observed without evident long-term effects ([Viguera et al. 2007a](#)). The study authors concluded that breast feeding in the context of lithium therapy may be considered reasonable for a healthy infant when the mother's bipolar disorder is clinically stable, lithium monotherapy or a simple medication regimen is being used, and the pediatrician is supportive of the mother's breast feeding while she is being treated with lithium.

---

## Side Effects and Toxicology

---

### Laboratory Monitoring

Before lithium therapy is started, a medical history should be obtained, as well as baseline renal laboratory tests

(blood urea nitrogen, creatinine level), thyroid function tests, and an electrocardiogram for patients older than 40 years ([American Psychiatric Association 2002](#), [McKnight et al. 2012](#)). The American Psychiatric Association practice guideline for the treatment of bipolar disorder suggests that renal function should be assessed every 2-3 months and thyroid function should be tested once or twice during the first 6 months of treatment. After the first 6 months, renal laboratory tests and thyroid function tests should be monitored every 6-12 months or as clinically indicated ([American Psychiatric Association 2002](#); [McKnight et al. 2012](#); [Shine et al. 2015](#)).

## Cognitive Side Effects and Weight Gain

Cognitive side effects and weight gain have been reported to be the most disturbing side effects experienced in patients receiving lithium maintenance treatment, whereas self-reported noncompliance was mostly associated with lithium's effects on cognition and coordination ([Gitlin et al. 1989](#)). [Stoll et al. \(1996\)](#) reported on a case series in which seven patients with lithium-associated cognitive deficits improved when switched to treatment with divalproex sodium. Lithium is associated with clinically significant weight gain (>7%) ([McKnight et al. 2012](#)), which may pose a greater risk for patients who are obese before commencement of lithium treatment compared with those who are at normal weight ([Bowden et al. 2006](#)).

## Neurotoxicity

Neurotoxicity, delirium, and encephalopathy have been reported with lithium use. Specific populations with underlying neurological vulnerability have been noted to be at higher risk. Also, certain circumstances, such as concomitant electroconvulsive therapy or use of other psychotropics—especially first-generation antipsychotics—have been found to increase the risk of neurotoxic adverse effects from lithium treatment.

Neurotoxic reactions are potentially irreversible. Permanent neurological deficits reported after episodes of lithium intoxication ([Apte and Langston 1983](#); [Donaldson and Cuningham 1983](#)) have included deficits in recent memory, ataxia, and movement disorders. Early hemodialysis may help prevent permanent sequelae in these cases. [Donaldson and Cuningham \(1983\)](#) also reported persistent neurological sequelae of lithium toxicity involving multiple sites within the nervous system. In a case series of 90 patients, [Adityanjee et al. \(2005\)](#) reported that the most common sequela was cerebellar dysfunction. The typical neurological signs of irreversible lithium neurotoxicity include cerebellar dysfunction, extrapyramidal symptoms, brainstem dysfunction, and dementia ([Ivkovic and Stern 2014](#)). [Himmelhoch et al. \(1980\)](#) found a greater incidence of lithium-induced neurotoxicity in the elderly. Other risk factors include longer duration of exposure to higher lithium levels and presence of medical comorbidities, including nephrogenic diabetes insipidus, abnormal thyroid function and impaired renal function, preexisting neurological disease, and drug combinations including antipsychotics ([Ivkovic and Stern 2014](#); [Netto and Phutane 2012](#); [Oakley et al. 2001](#)).

# Tremor

A fine postural tremor affects between 4% and 65% of patients who receive lithium ([Gelenberg and Jefferson 1995](#)). A severe tremor may indicate toxicity. Elimination of caffeine may actually worsen tremor because renal lithium clearance can be reduced with reduction of caffeine intake ([Jefferson 1988](#)). Lithium tremor, which resembles essential tremor, may worsen with age.

# Thyroid Abnormalities

In a chart review of 135 patients who received maintenance treatment with lithium, 38% had abnormal values on thyroid function tests (thyroid-stimulating hormone and/or free thyroxine index), with an association between laboratory abnormalities and length of time on lithium ([Fagiolini et al. 2006](#)). In a systematic review and meta-analysis, [McKnight et al. \(2012\)](#) reported that in comparison with placebo-treated subjects, lithium-treated patients had a sixfold higher risk of hypothyroidism and increased levels of thyroid-stimulating hormone. In a retrospective study of 209 patients who received lithium, [Kirov \(1998\)](#) found that 14.9% of the females and 3.4% of the males developed hypothyroidism. Female patients and patients older than 50 years were more likely to develop hypothyroidism ([Kirov 1998](#); [Shine et al. 2015](#)). Other reports have suggested that subclinical hypothyroidism during lithium therapy is much more common than previous cross-sectional studies had indicated ([Lombardi et al. 1993](#)). A family history of thyroid disease may lead to earlier onset of the hypothyroidism that occurs with lithium

use ([Kusalic and Engelsmann 1999](#)). Female patients with high serum lithium concentrations should have regular thyroid function testing ([Shine et al. 2015](#)).

## Parathyroid Abnormalities

Lithium has been associated with hypercalcemia and hyperparathyroidism ([Saunders et al. 2009](#)). A meta-analysis by [McKnight et al. \(2012\)](#) found that lithium-treated patients showed a 10% increase in levels of parathyroid hormone and calcium ([McKnight et al. 2012](#)) compared with control subjects. Similar increases in parathyroid hormone ([Albert et al. 2013](#)) and calcium ([Albert et al. 2013](#); [Shine et al. 2015](#)) in lithium-treated patients have been reported in other studies as well. Monitoring of calcium levels at baseline and yearly, or more frequently in the presence of clinical symptoms, is suggested ([McKnight et al. 2012](#)).

## Renal Complications

Lithium has multiple renal effects, including those that occur early in treatment and those that occur with chronic use. Lithium can induce tubular dysfunction early in treatment, with reduced urinary concentrating capacity developing over the first 8 weeks of treatment. Nephrogenic diabetes insipidus occurs in 20%–87% of patients on lithium ([Azab et al. 2015](#); [Markowitz et al. 2000](#); [Stone 1999](#)). These effects may be partially mediated by lithium's action on water and sodium channels in the kidney ([Grünfeld and Rossier 2009](#)); thus, there has been renewed interest in using amiloride, a sodium channel-blocking

diuretic, in an attempt to modify lithium's toxicity ([Azab et al. 2015](#); [Bedford et al. 2008](#)).

Another important renal effect of lithium is chronic kidney disease, which tends to occur after 10–20 years of lithium treatment ([Presne et al. 2003](#)) at an estimated prevalence of 1.2% ([Bendz et al. 2010](#)) to 21% ([Lepkifker et al. 2004](#)), depending on the definition of renal insufficiency used. However, the risk of progressing to end-stage renal disease is small (0.5%–1%) ([Bendz et al. 2010](#); [Tredget et al. 2010](#)). The clearest risk factors are duration of lithium use ([Bendz et al. 2010](#); [Bocchetta et al. 2015](#); [Castro et al. 2016](#); [Presne et al. 2003](#)), dosing of lithium more than once a day ([Castro et al. 2016](#)), and higher serum lithium levels ([Castro et al. 2016](#); [Shine et al. 2015](#)); however, additional possible risk factors are older age ([Bendz et al. 2010](#); [Bocchetta et al. 2015](#); [Castro et al. 2016](#); [Close et al. 2014](#); [Presne et al. 2003](#)), female sex ([Castro et al. 2016](#); [Shine et al. 2015](#)), previous episodes of lithium toxicity, and presence of comorbid disorders ([Castro et al. 2016](#); [Lepkifker et al. 2004](#)). The potential for chronic renal disease is the reason that close laboratory monitoring is required for patients on long-term lithium treatment ([Shine et al. 2015](#)). Once-daily dosing and maintaining low lithium levels when possible may be helpful in preventing long-term renal damage ([Castro et al. 2016](#); [Malhi and Tanious 2011](#)). The decision of whether to stop lithium in the setting of renal impairment must be made collaboratively by the patient, the psychiatrist, and the nephrologist. Chronic kidney disease can progress to renal failure even after lithium is stopped; however, with mild or moderate renal dysfunction, there may be improvement if a change is made ([Grünfeld and Rossier 2009](#)).

# Cardiac Changes

Lithium intoxication has been reported to cause cardiac alterations, including sinus bradycardia and sinus node dysfunction ([Steckler 1994](#)). Sinus node dysfunction was found to be more prevalent among patients who had been taking lithium for at least a year than among age-matched control subjects, although clinically significant dysfunction was uncommon ([Rosenqvist et al. 1993](#)). Also, cases of atrioventricular block in patients with therapeutic lithium levels have been reported ([Martin and Piascik 1985](#)). Electrocardiographic T-wave changes, as well as ventricular irritability, may occur ([Mitchell and Mackenzie 1982](#)). In patients with clinical indications for lithium use, the presence of cardiovascular disease does not constitute a contraindication to lithium use. Dosage adjustment and frequent cardiac monitoring are essential for the safe use of lithium in patients with cardiac disease ([Tilkian et al. 1976](#)). Because of the risk of sinus node dysfunction and other cardiac effects, careful monitoring of the pulse and electrocardiographic monitoring are recommended in patients older than 50 years ([Roose et al. 1979](#)).

---

## Drug-Drug Interactions

---

### Lithium With Other Mood Stabilizers

#### Lithium With Anticonvulsants

Lithium is commonly used in combination with other mood stabilizers, and although such combinations can be

synergistic, polypharmacy may increase the risk of adverse reactions ([Freeman and Stoll 1998](#); [Lenox et al. 1996](#)). The combination of lithium and valproate is often used in refractory mania. Interactions may include additive side effects, such as sedation, tremor, or weight gain, but the pharmacokinetics of lithium are not altered by the addition of valproate ([Granneman et al. 1996](#)). Lithium and carbamazepine have been combined for bipolar disorder refractory to lithium alone, but this combination may increase the risk of neurotoxicity ([Chaudhry and Waters 1983](#); [Frances et al. 1996](#); [Kishimoto 1992](#); [Shukla et al. 1984, 1985](#); [Small et al. 1995](#)). Topiramate exhibits no pharmacokinetic interactions with lithium ([Bialer et al. 2004](#)). There are inconsistent reports about interactions between lithium and lamotrigine; whereas [Chen et al. \(1999\)](#) found no significant alterations in the pharmacokinetics of lithium in 20 healthy volunteers, another study showed that co-treatment with lithium may lower the serum concentration of lamotrigine ([Reimers et al. 2005](#)). Gabapentin is also used adjunctively in the treatment of bipolar disorder, and because gabapentin has no known drug interactions, it is likely safe with lithium use ([Frye et al. 1998](#); [Vollmer et al. 1986](#)). Benzodiazepines also do not interact with lithium ([Adler 1986](#); [Modell et al. 1985](#); [Sachs et al. 1990a, 1990b](#)).

## **Lithium With Antipsychotics**

Although many investigators have reported safe and efficacious results from combining lithium and first-generation antipsychotics ([Baastrup et al. 1976](#); [Bigelow et al. 1981](#); [Carman et al. 1981](#); [Garfinkel et al. 1980](#); [Goldney and Spence 1986](#)), neurotoxicity and even tardive dyskinesia can occur ([Cohen and Cohen 1974](#); [Dinan and](#)

Kohen 1989; Mani et al. 1996; Mann et al. 1983; Miller et al. 1986; Perényi et al. 1983, 1984; Spring 1979; Spring and Frankel 1981). Goodwin and Jamison (1990) recommended that when incorporating a first-generation antipsychotic into a regimen of lithium therapy, the antipsychotic should be used at lower dosages, and lithium levels should be maintained below 1.0 mEq/L.

The use of lithium with second-generation antipsychotics also may result in adverse reactions. Use of clozapine with lithium may cause diabetic ketoacidosis, neuroleptic malignant syndrome, and neurological side effects (Blake et al. 1992; Garcia et al. 1994; Lemus et al. 1989; Peterson and Byrd 1996; Pope et al. 1986). Some investigators have reported safe and effective use of risperidone and lithium (Ghaemi et al. 1997; Tohen et al. 1996), although adverse effects, including fever, increased white blood cell counts, increased creatine phosphokinase levels, and delirium, also have been reported (Chen and Cardasis 1996; Swanson et al. 1995). Preliminary data suggest that the combination of lithium and olanzapine is efficacious and well tolerated in acute mania (Madhusoodanan et al. 2000; Sanger et al. 2001). Quetiapine coadministered with lithium did not result in clinically important pharmacokinetic interactions (Potkin et al. 2002). Augmentation of lithium with aripiprazole produced rapid and significant improvement in manic symptoms that was sustained over the long term (Vieta et al. 2008), and there were no clinically meaningful effects on the pharmacokinetics of either drug (Boulton et al. 2012). There were no significant interactions between lurasidone and lithium, and no dosage adjustment for lurasidone was needed when administered with lithium (Chiu et al. 2014).

# Lithium With Antidepressants

Lithium is often used concomitantly with antidepressants in the treatment of bipolar depression and refractory unipolar depression. Serotonin syndrome—a constellation of mental status and behavioral changes (either agitation or sedation), motor symptoms (restlessness, weakness, hyperreflexia, or ataxia), and autonomic dysfunction (nausea and/or vomiting, dizziness, sweating, fever) ([Lejoyeux et al. 1994](#))—has been reported with the use of lithium and serotonergic antidepressants ([Adan-Manes et al. 2006](#); [Fagiolini et al. 2001](#); [Karle and Bjørndal 1995](#); [Mekler and Woggon 1997](#); [Muly et al. 1993](#); [Ohman and Spigset 1993](#); [Shahani 2012](#); [Sobanski et al. 1997](#)).

# Lithium With Nonpsychotropic Medications

When lithium is used concurrently with nonsteroidal anti-inflammatory drugs, signs and symptoms of toxicity and lithium levels must be monitored more carefully because nonsteroidal anti-inflammatory drugs increase the risk of toxicity ([Grandjean and Aubry 2009](#); [Johnson et al. 1993](#)).

Because lithium excretion relies on renal clearance, diuretic medications may affect lithium levels, depending on their site of action. Thiazide diuretics trigger a compensatory increase in reabsorption in the proximal tubule and lead to elevations in lithium levels, whereas loop diuretics do not promote lithium reabsorption and do not greatly affect lithium levels ([Finley et al. 1995](#)). Osmotic diuretics enhance lithium excretion and may serve to

counteract lithium toxicity, and either no change or a slight increase in lithium levels has been reported with potassium-sparing diuretics.

Neurotoxic and other adverse reactions have been associated with the concomitant administration of lithium with calcium channel blockers ([Dubovsky et al. 1987](#); [Finley et al. 1995](#); [Helmuth et al. 1989](#); [Wright and Jarrett 1991](#)). Angiotensin-converting enzyme inhibitors or angiotensin receptor 1 blockers may raise lithium levels ([DasGupta et al. 1992](#); [Finley et al. 1996](#); [Lazarczyk and Giannakopoulos 2014](#)). Serum lithium levels may increase in the context of sodium restriction ([Bennett 1997](#)). Theophylline and caffeine can decrease lithium concentrations ([Cook et al. 1985](#)). Lactulose may result in lithium toxicity, possibly by volume depletion, as reported in a case series ([Bregman et al. 2014](#)).

---

## Conclusion

---

Lithium is an important option in the evidence-based rational treatment of bipolar disorder. Bipolar disorder affects between 1% and 5% of the population ([Akiskal et al. 2000](#)) and causes significant morbidity and mortality, and the diagnosis of bipolar disorder carries a high risk for suicide. A summary published in 1990 estimated that 25%–50% attempt suicide and 19% complete suicide ([Goodwin and Jamison 1990](#)); however, a recent analysis estimated that the pooled suicide rate for bipolar disorder was 164 per 100,000 person-years, with individuals with bipolar disorder accounting for 3.4%–14% of all suicide deaths ([Schaffer et al. 2015](#)).

Lithium has been shown to be effective for acute mania and bipolar depression and as a prophylactic treatment for bipolar disorder. Some data suggest that conditions such as comorbid neurological illness and mixed episodes may be indicators of illness that is more responsive to mood stabilizers other than lithium. Evidence also suggests that lithium can play a role in the treatment of refractory unipolar depression in patients at risk for suicide. Lithium may be less risky than anticonvulsants in pregnancy. Although we continually seek new treatments and hope that they will be more efficacious and better tolerated than older medications, for now lithium remains an important treatment option.

# CHAPTER 37

## Valproate

Charles L. Bowden, M.D.

---

### History and Discovery

---

Valproate was the first mood stabilizer to be studied as an alternative to lithium ([Lambert et al. 1966](#)). An enteric-coated formulation, divalproex sodium, was approved in the United States for the treatment of mania in 1995. An extended-release (ER) formulation of divalproex was approved for migraine in 2001 and for mania in 2006. Valproate, either as divalproex or as other formulations, is now approved worldwide for the treatment of mania.

---

### Pharmacological Profile

---

Valproic acid (dipropylacetic acid; [Figure 37-1](#)) is an eight-carbon, branched-chain carboxylic acid that is structurally distinct from other antiepileptic and psychotropic compounds ([Bocci and Beretta 1976](#); [Levy 1984](#)). Its three-

dimensional structure overlays that of naturally occurring fatty acids (e.g., oleic and linolenic acids). Valproate binds in a saturable manner to the neuronal membrane sites to which these longer-chain fatty acids attach. Some of valproate's molecular mechanisms are likely a consequence of this physiochemical property.

---

**FIGURE 37-1.** Chemical structure of valproic acid.

---

## Pharmacokinetics and Disposition

---

Valproate is commercially available in the United States in five oral preparations: 1) divalproex sodium, an enteric-coated, stable-coordination compound containing equal proportions of valproic acid and sodium valproate in a 1:1 molar ratio; 2) valproic acid; 3) sodium valproate; 4) divalproex sodium sprinkle capsule (containing coated particles of divalproex sodium), which can be ingested intact or pulled apart and contents sprinkled on food; and 5) an extended-release form of divalproex that provides once-daily dosing and a substantially flatter peak-to-trough ratio. Sodium valproate is available for intravenous use and,

as such, has been demonstrated to provide reduction in manic symptoms within 1 day or less (Grunze et al. 1999). Valproate can also be compounded in suppository form for rectal administration. The valproate ion is the common compound in plasma.

The bioavailability of valproate approaches 100% with all preparations (Wilder 1992). With the exception of divalproex sodium, all preparations taken orally are rapidly absorbed. Sodium valproate and valproic acid attain peak serum concentrations within 2 hours. Divalproex sodium reaches peak serum concentrations within 3–8 hours. The ER form of divalproex sodium has an earlier onset of absorption than the regular-release tablets and approximately a 20% smaller difference in trough and peak serum levels than regular-release divalproex (Figure 37-2).

**FIGURE 37-2.** Mean plasma valproate concentrations with different formulations.

Valproate is highly protein bound, predominantly to serum albumin and proportional to the albumin concentration. Although patients with low levels of albumin have a higher fraction of unbound drug, the steady-state level of total drug is not altered. Only the unbound drug crosses the blood-brain barrier and is bioactive. Thus, when valproate is displaced from protein-binding sites through drug interactions, the total drug concentration may not change; however, the pharmacologically active unbound drug does increase and may produce signs and symptoms of toxicity. Moreover, when the plasma concentration of valproate rises in response to dosage increases, the amount of unbound (active) valproate increases disproportionately and is metabolized, with an apparent increase in clearance of total drug, yielding lower-than-expected total plasma concentrations ([Levy 1984](#); [Wilder 1992](#)) ([Figure 37-3](#)). In addition, protein binding of valproate is increased by low-fat diets and decreased by high-fat diets. Because of lower serum protein levels, women and elderly patients will generally have a higher proportion of the active free moiety.

**FIGURE 37-3.** Total valproate (VPA) concentrations in the presence of.

As the total concentration of VPA increases, protein-binding sites become saturated, and the percentage of unbound to bound VPA increases.

The concentration range required for good clinical effect in mania is approximately 45–125 µg/mL ([Bowden et al. 1996](#)). Patients who are able to tolerate higher serum levels—up to around 125 µg/mL—may experience greater improvement ([Allen et al. 2006](#)). An open report suggested that individuals with rapid cycling in the context of bipolar II disorder or cyclothymic disorder may respond to serum valproate concentrations of less than 50 µg/mL ([Jacobsen 1993](#)). In maintenance treatment, patients whose serum valproate levels were maintained between 75 and 99 µg/mL

had superior outcomes compared with patients whose serum levels were either lower or higher than this range ([Keck et al. 2005](#)). Valproate is metabolized in the liver, primarily through glucuronidation.

When used for the treatment of bipolar disorder, valproate is usually begun at a dosage of 15–20 mg/kg/day. The drug can be “orally loaded” at 20–30 mg/kg/day in patients with acute mania to induce a more rapid response. The dosage of valproate is increased according to the patient’s response and tolerance of side effects, usually by 250–500 mg/day every 1–3 days, to serum concentrations of 45–125 µg/mL. Of note, sedation, increased appetite, and reductions in white blood cell counts and platelet counts all become more frequent at serum concentrations greater than 100 µg/mL ([Bowden et al. 2000](#)).

---

## Mechanism of Action

---

Valproate stimulates extracellular signal-regulated kinase (ERK) and indirectly inhibits glycogen synthase kinase 3 (GSK-3) ([Cournoyer and Desrosiers 2009](#)). Valproate also stimulates the activity of bcl-2, a neuroprotective substance ([Gray et al. 2003](#)). Valproate inhibits histone deacetylase, and many of the drug’s subcellular effects (e.g., increasing brain-derived neurotrophic factor) are likely a consequence of this action ([Harwood and Agam 2003](#); [Perova et al. 2010](#)).

---

## Indications and Efficacy

---

# Acute Mania in Bipolar Disorder

In a placebo-controlled study, patients with more severe manic symptoms experienced greater benefits from valproate versus placebo than did patients with milder manic symptomatology ([Bowden et al. 2006](#)). In this study, the antimanic response to valproate occurred as early as 5 days following initiation of treatment.

Valproate has been studied in adjunctive regimens with various antipsychotics, with findings consistently pointing to greater efficacy for combination treatment than for monotherapy ([Bowden 2011](#); [Marcus et al. 2011](#); [Müller-Oerlinghausen et al. 2000](#); [Tohen et al. 2002](#); [Yatham et al. 2003](#)). A 3-week double-blind, placebo-controlled study ([Sachs et al. 2002](#)) evaluated the efficacy of risperidone or haloperidol in combination with a mood stabilizer in two groups of bipolar patients: 1) patients who had received treatment with either valproate or lithium at an adequate dosage for at least 2 weeks and were still manic (in which case they were randomly assigned to add-on treatment with risperidone, haloperidol, or placebo) and 2) patients who were manic but had not yet received mood stabilizer treatment (in which case either lithium or valproate was started concurrently with randomization to the add-on treatment). Patients who started mood stabilizer treatment on entering the study showed no advantage from the add-on antipsychotic, whereas patients who were already receiving valproate or lithium but were still symptomatic at study entry *did* demonstrate an advantage from the combination treatment ([Sachs et al. 2002](#)). These findings suggest that in most circumstances, combination therapy is most effective in—and should be limited to—patients whose

symptoms have not responded to a relatively short period of adequate monotherapy treatment.

Few studies of any antimanic agent have addressed its effectiveness in hypomanic episodes, which are more common than manic episodes, even in diagnostically bipolar I patients. In an 8-week randomized, double-blind, placebo-controlled study in outpatients with bipolar and related disorders manifesting hypomanic symptomatology (operationalized as a Young Mania Rating Scale (YMRS) score between 10 and 20), divalproex ER was significantly more effective than placebo in reducing hypomanic/mild manic symptoms ( $P=0.024$ ) and nonsignificantly more effective than placebo in improving depression ([McElroy et al. 2010](#)).

## Acute Depression in Bipolar Disorder

An 8-week randomized, placebo-controlled, blinded study reported that divalproex-treated subjects experienced significantly greater improvement than placebo-treated patients in both depressive and anxious symptomatology, based on Hamilton Rating Scale for Depression (Ham-D) and Hamilton Anxiety Scale (Ham-A) scores ([Davis et al. 2005](#)).

In a 6-week randomized, blinded study in bipolar depression, divalproex was superior to placebo, with primary improvement noted on core mood symptoms rather than on anxiety or insomnia ([Ghaemi et al. 2007](#)). [Smith et al. \(2010\)](#) conducted a meta-analysis of these and two other small randomized, blinded studies in acute bipolar depression and found significant reductions in depression scale scores for valproate compared with placebo

(standardized mean difference:  $-0.35$ ; range:  $-0.69$  to  $-0.02$ ). Tolerability was good, but improvement of anxiety was modest and not significant. Valproate also has shown significant prophylactic benefit in reducing risk of relapse to depression, both as monotherapy and as an adjunct to selective serotonin reuptake inhibitor (SSRI) treatment. In a 1-year randomized, double-blind study of bipolar patients who were initially manic, divalproex was more effective than lithium or placebo in delaying time to clinical depression ([Gyulai et al. 2003](#)). In those subjects who developed depression, divalproex augmented with either paroxetine or sertraline was superior to either antidepressant alone in treatment of the depression ([Gyulai et al. 2003](#)). [Ketter et al. \(2011\)](#) calculated a number needed to treat (NNT) of 11 for divalproex in prevention of bipolar depression; by comparison, an NNT of 49 was calculated for lithium, 15 for lamotrigine, 12 for olanzapine, and 64 for aripiprazole ([Ketter et al. 2011](#)).

## Maintenance Treatment of Bipolar Disorder

One large double-blind, placebo-controlled maintenance study of valproate monotherapy has been published ([Bowden et al. 2000](#)). Patients who recovered with open treatment with either divalproex or lithium were randomly assigned to maintenance treatment with divalproex, lithium, or placebo. The divalproex group did not differ significantly from the placebo group on time to any mood episode ( $P=0.06$ ), in part because the rate of relapse to mania with placebo was lower than anticipated. However, a post hoc analysis of the study data found that divalproex

was superior to placebo on secondary outcome measures, with lower rates of discontinuation for either any recurrent mood episode or a depressive episode ([Bowden 2004](#)). Divalproex was superior to lithium on some comparisons, including longer duration of successful prophylaxis in the study and less deterioration in depressive symptom scores. Among the subset of patients who received divalproex in the open acute phase, those randomly assigned to receive divalproex in the double-blind maintenance phase had significantly longer times to recurrence of any mood episode ( $P=0.05$ ) or a depressive episode ( $P=0.03$ ), and the proportion of patients who completed the 1-year study without developing either a manic or a depressive episode was significantly higher for divalproex-treated patients than for placebo-treated patients (41% vs. 13%;  $P=0.01$ ) ([Bowden et al. 2000](#)). This study ([Bowden et al. 2000](#)) is the only investigation published to date that has allowed a statistical test of the relation between acute-episode response to treatment and maintenance treatment outcomes. A post hoc review of the study that used relative risk analysis found that patients taking divalproex were significantly less likely than those taking placebo to have prematurely left the study because of a mood episode (relative risk [RR]=0.63; 95% confidence interval [CI]=0.44-0.90) ([Bowden 2004](#)). A post hoc analysis of time to any mood episode or early discontinuation for any reason, a measure of effectiveness that has been incorporated in more recent maintenance studies in bipolar disorder, indicated a significant advantage for divalproex over lithium ( $P>0.004$ ) ([Bowden 2003a](#)).

A comparison of valproate and lithium in a randomized, blinded trial of rapid-cycling patients reported that only one-quarter of the patients enrolled met criteria for an

acute bimodal response to either drug, with fewer than 25% of the patients who entered the randomized maintenance phase retaining benefit without relapse for the entire 20-month period. These findings indicate that monotherapy regimens with either valproate or lithium are unlikely to be effective in more than a small minority of rapid-cycling patients ([Calabrese et al. 2005](#)).

Additional evidence of the low likelihood of maintaining remission comes from a study of bipolar patients with a recently remitted manic episode who were followed up for 6 months of continuation valproate or lithium plus adjunctive therapy consisting of random assignment to either olanzapine or risperidone. The adjunctive therapy reduced the proportion relapsed among patients randomized to olanzapine, but not among patients randomized to risperidone ([Yatham et al. 2016](#)). In a systematic review and meta-analysis of randomized controlled maintenance treatment studies in bipolar disorder, lithium plus valproate seemed to be more effective in preventing manic episodes than in preventing depressive episodes. Lamotrigine appeared to be more protective against depressive episodes. The analyses suggested that the combination was likely to be superior to either drug alone ([Miura et al. 2014](#)).

Older adults with bipolar disorder have high rates of hospitalization for medical conditions. In a large cohort study of bipolar patients ages 66 years or older who had recently been discharged from a psychiatric hospitalization, 1-year rates of acute medical, nonpsychiatric health use did not differ according to which medication—lithium, valproate, or another agent (e.g., antipsychotics)—patients were receiving ([Rej et al. 2015](#)). Along with male sex and a history of medical hospitalization, severity of mental illness

(e.g., being hospitalized for bipolar disorder) may be a more important driver of future acute medical health service use compared with choice of pharmacotherapy. A proactive collaborative approach with primary care and home care may potentially prevent intensive acute medical health service use in older adults with bipolar disorder and other severe mental illnesses.

Over the past decade, more studies employing enriched designs in adjunctive treatment have been conducted for all drugs. Such studies are more likely to yield superiority for the adjunctive regimen, because the only patients eligible are those who have failed to respond to monotherapy regimens. Most of these studies have added atypical antipsychotics—or, in one case, lamotrigine—to regimens of valproate or lithium. Despite the design inequality, the designs have the merit of following a common pattern of clinical practice. In all of these studies, valproate has been adequately tolerated along with the added drug. In most adjunctive design studies, no separate analysis of the results for valproate and lithium has been reported. In a study of adjunctive ziprasidone or placebo added to the regimens of patients who continued to have manic symptoms while taking valproate or lithium, the adjunctive therapy was superior to continued lithium monotherapy, whereas the outcome of valproate monotherapy was equal to that of valproate plus ziprasidone ([Bowden 2011](#)).

A 12-week randomized, blinded comparison of valproate and olanzapine showed equivalent efficacy in mania for the two treatments ([Zajecka et al. 2002](#)). A 47-week study of the two drugs reported low rates of completion for both treatments (15% vs. 16%), with earlier symptomatic remission with olanzapine but equivalent efficacy for the two drugs over the remaining portion of the study ([Tohen et](#)

[al. 2003](#)). For both drugs, patients who were in remission at the end of week 3 of treatment were significantly more likely to complete the 47-week trial compared with those who were not in remission at that point (divalproex: 26.2% vs. 11.1%; olanzapine: 20.3% vs. 10.6%;  $P=0.001$ ). This finding indicates that acute treatment response to a drug (either valproate or olanzapine) during a manic episode is predictive of effective treatment with that drug in maintenance therapy. In both studies, weight gain was greater with olanzapine than with divalproex, and divalproex was associated with a significant reduction in cholesterol levels, compared with an increase in cholesterol levels with olanzapine ([Tohen et al. 2003](#); [Zajecka et al. 2002](#)).

## Mania Secondary to Head Trauma or Neurodevelopmental/Neurodegenerative Disorders

Evidence suggesting that secondary or complicated mania responds well to valproate is mixed. In an open study of 56 valproate-treated patients with mania, response was associated with the presence of nonparoxysmal abnormalities on the electroencephalogram, but not with neurological soft signs or abnormalities on computed axial tomography scans of brain ([McElroy et al. 1988](#)). A study from the 1980s ([Pope et al. 1988](#)) had suggested that manic patients who had experienced a closed-head injury before the onset of bipolar disorder were more likely to respond successfully to valproate treatment for mood symptoms. Furthermore, case reports have described successful

valproate treatment of mood symptoms in individuals with DSM-III ([American Psychiatric Association 1980](#)) organic brain syndromes ([Kahn et al. 1988](#)) and of bipolar symptoms in patients with DSM-III mental retardation ([Kastner et al. 1990](#); [Sovner 1989](#)).

## Bipolar Disorder in Children and Adolescents

Few adequately powered and designed studies have been conducted in pediatric bipolar disorder. Findings from the first placebo-controlled trial of divalproex in bipolar children and adolescents (ages 10–17 years) indicated that divalproex was not significantly superior to placebo, and side effects were similar for divalproex and placebo ([Wagner et al. 2009](#)).

In the only blinded, randomized study to compare two medications in young adolescent patients with bipolar disorder, risperidone compared with valproate showed somewhat earlier onset of improvement and resulted in a higher proportion of patients responding by the end of the 6-week trial ([Pavuluri et al. 2010](#)). This study lacked a placebo control group.

Attention-deficit/hyperactivity disorder (ADHD) symptoms are commonly intertwined with specific symptoms of bipolar disorder in youth. In a pragmatic study of 40 patients between the ages of 6 and 17 years with bipolar I (77%) or bipolar II (23%) disorder, YMRS scores of 14 or greater, and ADHD symptomatology, subjects were first given divalproex. Thirty-two subjects achieved improvement of 50% or greater on YMRS scores, whereas only 3 showed improvement in ADHD symptoms. Mixed amphetamines or

placebo were then added to the regimens of the 30 subjects who entered the placebo crossover phase. Amphetamines plus divalproex were superior to divalproex alone in improving ADHD symptoms. Both regimens were well tolerated, and no patient experienced worsening of manic symptoms ([Scheffer et al. 2005](#)).

In a double-blind, randomized, placebo-controlled study in children ages 8–10 years who met criteria for oppositional defiant disorder or conduct disorder and had experienced temper and mood lability but did not meet full criteria for bipolar disorder, patients were randomly assigned to 6 weeks of divalproex or placebo, followed by 6 weeks of placebo or divalproex (in a crossover design). By the end of the first phase, 8 of the 10 patients who received divalproex had responded, compared with none of those who received placebo. Of the 15 patients who completed both phases, 12 had superior responses to divalproex ([Donovan et al. 2000](#)).

## Agitation and Clinical Decline in Elderly Patients With Dementia

Patients with dementia are frequently institutionalized for agitation and behavioral disturbances. In a randomized, blinded study in which 56 nursing home patients with agitation and dementia received either placebo or individualized doses of divalproex, the drug-placebo difference on Brief Psychiatric Rating Scale Agitation scores significantly favored divalproex. Side effects occurred in 68% of the divalproex group versus 33% of the placebo group and were generally rated as mild ([Porsteinsson et al. 2001](#)). Six weeks of open continuation treatment resulted in

further improvement of agitation. Divalproex serum levels were greater than 40 µg/mL in both the acute blinded phase and the open continuation phase ([Porsteinsson et al. 2003](#)). Patients with dementia should generally receive valproate dosages lower than 1,000 mg/day to ensure adequate tolerability ([Profenno et al. 2005](#)). A small randomized, placebo-controlled study of valproate in the treatment of aggression in dementia failed to find any difference between valproate and placebo, although the fixed dosage used (valproate 480 mg/day) may have been inadequate ([Sival et al. 2002](#)).

Valproate also was studied for its potential utility in preventing or delaying illness progression in 313 nursing home residents with moderate Alzheimer's disease who had not yet experienced agitation or psychosis. Time to emergence of clinically significant agitation or psychosis did not differ between valproate and placebo groups, and valproate was associated with serious adverse effects in the patients ([Tariot et al. 2011](#)). Taken in the aggregate, these studies suggest that although valproate at relatively low dosages can improve dementia-related agitation in some patients, valproate has no utility in slowing or preventing disease progression in Alzheimer's dementia.

## Irritability and Aggression

Valproate has been reported to be effective in reducing irritability and aggression among diverse patient populations, including individuals with autism spectrum disorders or personality disorders. In a 12-week double-blind study of children and adolescents with autism spectrum disorders, irritability measures were significantly

improved with divalproex compared with placebo. Overall, 62% of the divalproex-treated subjects versus 9% of the placebo subjects (odds ratio=16.7) were responders ([Hollander et al. 2010](#)).

In a randomized, placebo-controlled, double-blind study, 249 patients with Cluster B personality disorders, intermittent explosive disorder, or posttraumatic stress disorder were treated for 12 weeks with either divalproex or placebo. Although divalproex did not separate from placebo in the combined analysis of all patient groups, aggression and irritability scores among the 96 Cluster B patients showed significant improvement over the course of the study ([Hollander et al. 2003](#)).

## Co-Therapy in Schizophrenia

Adjunctive use of valproate in the treatment of schizophrenia has increased, with one report indicating that more than one-third of psychiatric inpatients with a diagnosis of schizophrenia received valproate during hospitalization ([Citrome et al. 2000](#)). In a 4-week randomized, double-blind study, 242 schizophrenic patients were assigned to receive either monotherapy with an antipsychotic (risperidone or olanzapine) or adjunctive treatment with divalproex plus the antipsychotic drug. Compared with patients receiving monotherapy, those who received combination therapy showed significantly greater improvement on Positive and Negative Syndrome Scale (PANSS)-Total and PANSS positive symptom subscale scores from day 3 through day 21, but not at day 28. Platelet counts decreased with combination therapy. Cholesterol levels increased with olanzapine or risperidone

monotherapy compared with the significantly lower levels seen with the combination treatment. Weight gain did not differ for patients receiving olanzapine versus patients receiving divalproex plus olanzapine; however, weight gain was greater for divalproex plus risperidone (7.5 lbs) than for risperidone (4.2 lbs) ([Casey et al. 2003](#)).

## Bipolar Disorder With Comorbid Alcohol Use Disorder

Bipolar disorder is often associated with substance use disorders, particularly alcoholism. In the largest prospective, blinded, placebo-controlled study, 59 bipolar I patients with DSM-IV ([American Psychiatric Association 1994](#)) alcohol dependence were treated with lithium carbonate and psychosocial interventions for 24 weeks, with half randomly assigned to receive adjunctive valproate. The addition of valproate was associated with significantly fewer heavy drinking days, fewer drinks per heavy drinking day, and fewer drinks per drinking day. Higher serum valproate concentrations were correlated with improved alcohol use outcomes. Both manic and depressive symptoms improved equivalently ([Salloum et al. 2005](#)).

In a 12-week double-blind, placebo-controlled trial, divalproex treatment was associated with a significantly reduced rate of relapse to heavy drinking, but no significant differences were found in other alcohol-related outcomes. Significantly greater decreases in irritability were found in the divalproex-treated group, but no significant between-group differences were seen on measures of impulsivity ([Brady et al. 2002](#)).

---

# Predictors of Positive Response to Valproate Versus Lithium

---

## Mixed Mania

Patients with mixed manic presentations experienced greater symptom improvement with divalproex than with lithium treatment in two randomized studies ([Freeman et al. 1992](#); [Swann et al. 1997](#)), one of which (Swann et al.) was placebo controlled (reviewed in [Bowden 1995](#)). Patients with mixed manic symptoms and patients with pure manic symptoms showed equivalent improvement with divalproex, a finding that indicates the drug's broad efficacy across mania subtypes ([Swann et al. 1997](#)). By contrast, during maintenance treatment, patients with mixed mania had equivalent responses to divalproex and lithium, with evidence of higher rates of adverse effects as a function of illness features of mixed mania, compared with rates of adverse effects in patients with euphoric mania ([Bowden et al. 2005](#); [Singh et al. 2013](#)). These results suggest that effective long-term management of mixed manic states requires medication regimens that are more complex than monotherapy.

## High Lifetime Number of Mood Episodes

Divalproex was significantly more effective than lithium among manic patients with a history of more than 10 mood

episodes ([Swann et al. 1999](#)) or more than two depressive episodes ([Swann et al. 2000](#)).

---

## Side Effects and Toxicology

---

Valproate has been extensively used over several decades; thus, its adverse-effect profile is well characterized ([DeVane 2003](#); [Prevey et al. 1996](#)). Compared with patients treated for migraine or mania, patients treated for epilepsy are more likely to experience adverse events consequent to the generally higher dosages of valproate required and the more complex drug regimens used in epilepsy. In a large 1-year placebo-controlled study in patients with bipolar disorder, tremor and weight gain were the only symptoms more commonly reported with divalproex than with placebo ([DeVane 2003](#)).

## Gastrointestinal Effects

Common gastrointestinal effects of valproate include nausea, vomiting, diarrhea, dyspepsia, and anorexia. These are dose dependent, are usually encountered at the start of treatment, and are often transient ([DeVane 2003](#)). Immediate-release formulations of valproic acid are more likely than ER and enteric-coated formulations to cause adverse events ([Horne and Cunanan 2003](#); [Zarate et al. 1999](#)).

## Tremor

Tremor consequent to valproate resembles benign essential tremor and may respond to a reduction in dosage. Use of the ER or enteric-coated formulation may lessen the frequency of tremor ([Wilder 1992](#); [Zarate et al. 1999](#)).

## Sedation

Mild sedation is common at initiation of valproate treatment. This adverse effect is dose dependent and may be minimized by dosage reduction, slower titration, use of ER formulations, or taking all medication at bedtime.

## Pancreatitis

Idiosyncratic acute pancreatitis is an infrequent adverse event associated with valproate. In clinical trials, rates of amylase elevation with valproate were similar to those with placebo ([Pellock et al. 2002](#)), suggesting that precautionary amylase levels offer little benefit in predicting pancreatitis. Therefore, clinicians should routinely assess patients' clinical symptoms to identify possible signs of pancreatitis.

## Hematological Effects

Leukopenia and thrombocytopenia are directly related to higher valproate serum levels, usually 100 µg/mL or greater ([Acharya and Bussel 1996](#); [Bowden et al. 2000](#)). Thrombocytopenia is usually mild and rarely associated with bleeding complications. Management consists of dosage reduction. Platelet counts below 75,000/mm<sup>3</sup> should be monitored and regularly reassessed, because counts

lower than this level are more frequently associated with bruising or bleeding ([Zarate et al. 1999](#)).

## Hepatotoxicity

None of the longer-term studies of the past decade and a half has found evidence of hepatic dysfunction or significant worsening of hepatic indices in valproate-treated patients compared with placebo-treated or comparator-treated patients ([Bowden et al. 2000](#); [Tohen et al. 2002](#); [Zajacka et al. 2002](#)).

The risk of liver toxicity from valproate is largely limited to patients younger than 2 years, in whom hepatic function is still immature ([Tohen et al. 2003](#)). In a long-term study of divalproex (versus lithium) in adult outpatients with bipolar I disorder, full-dosage regimens for 1 year were associated with improvements in laboratory indices of hepatic function, and no hepatotoxicity was reported in the 187 patients taking divalproex ([Bowden et al. 2000](#)). A 47-week placebo-controlled study of olanzapine augmentation of divalproex or lithium in outpatients with bipolar disorder likewise found no evidence of adverse hepatic effects among patients who received divalproex ([Tohen et al. 2003](#)).

One risk factor for the development of hepatotoxicity is concomitant administration of other anticonvulsants (e.g., carbamazepine, phenytoin) that cause induction of enzymes involved in the metabolism of valproate, leading to increased concentrations of an active and hepatotoxic metabolite, 2-propyl-4-pentenoic acid.

## Weight Gain

Weight gain of 3–24 lbs is seen in 3%–20% of patients taking valproic acid for periods ranging from 3 to 12 months ([Bowden 2003b](#)). Weight gain has been consistently less with valproate than with olanzapine in comparison studies (1.22 kg vs. 2.79 kg) ([Tohen et al. 2003](#); [Zajacka et al. 2002](#)). Valproate serum levels greater than 125 µg/mL are more likely than lower levels to cause weight gain ([Bowden 2000](#)). If increased appetite and weight gain occur with valproate, the dosage should be lowered so long as clinical effectiveness is maintained; alternatively, valproate should be discontinued and replaced with a regimen without risk of weight gain.

## Cognitive Effects

Valproate infrequently produces adverse effects on cognitive functioning, and it improves cognition in some patients ([Prevey et al. 1996](#)). In a 20-week randomized, observer-blinded, parallel-group trial, the addition of valproate to carbamazepine resulted in improvement in short-term verbal memory ([Aldenkamp et al. 2000](#)). No adverse cognitive effects associated with use of valproate were seen in a group of elderly patients (mean age=77 years) ([Craig and Tallis 1994](#)).

## Lipid Profile Effects

Several studies indicate that valproate significantly reduces total and low-density lipoprotein (LDL) cholesterol levels and increases high-density lipoprotein (HDL) cholesterol levels in long-term treatment ([Geller et al. 2012](#)), and that it protects against the adverse effects of some antipsychotic

drugs on lipid function ([Bowden et al. 2000](#); [Casey et al. 2003](#); [Tohen et al. 2003](#)). A 3-week study in mania indicated reductions in cholesterol, HDL, and LDL compared with placebo and reported the effect to be limited to those subjects who had total cholesterol levels of 200 mg/dL or greater at study entry ([Bowden et al. 2006](#)).

## Polycystic Ovarian Syndrome

The prevalence of menstrual disturbances in women with bipolar disorder is higher than that in the general population. A cross-sectional study of women found evidence of a higher rate of polycystic ovarian syndrome (PCOS) in subjects who reported valproate as a component of their prior treatment regimen ([Joffe et al. 2006](#)). A study of 10 lithium-treated, 10 valproate-treated, and 2 carbamazepine-treated women with bipolar disorder found a high frequency of menstrual dysfunction in all groups. Hormonal assessment of estrone, luteinizing hormone, follicle-stimulating hormone, testosterone, and dehydroepiandrosterone (DHEA) yielded no abnormal values in any patient ([Rasgon et al. 2000](#)). Obesity may be a mechanistic pathway whereby valproate (and potentially other drugs) predisposes women to PCOS. It is advisable to treat weight gain as a risk factor for possible development of PCOS and intervene as needed to avoid clinically significant weight gain.

## Hair Loss

Hair loss may occur early in treatment and is usually transient. Frequency of hair loss may be greater in women

than in men ([Lajee and Parsonage 1980](#)). Dosage reduction and separation of valproate dosing from meals can be helpful in controlling this effect; supplemental zinc and selenium ingestion via multivitamin tablets also may be useful.

## Use During Pregnancy and Lactation

### Teratogenic and Developmental Effects

Valproate is associated with an increased incidence of birth defects, including neural tube defects, craniofacial anomalies, limb abnormalities, and cardiovascular anomalies, if infants are exposed to valproic acid in the first 10 weeks of gestation ([Kinrys et al. 2003](#); [Samrén et al. 1997](#)). Neural tube defects, the most serious of the congenital anomalies, occur in 1%–4% of such infants. Most of the available data involved patients with epilepsy, who generally receive valproate dosages higher than those used for bipolar disorder and migraine and who are often concurrently taking other teratogenic anticonvulsants ([Bowden 2003b](#)). The risk of malformations is increased with higher dosages and higher serum levels of valproate, as well as with concomitant use of other anticonvulsants (because of higher concentrations of 2-propyl-4-pentenoic acid, a teratogenic agent); is possibly decreased with supplemental folic acid; and is definitely reduced with lower dosages of valproate ([Bowden 2003b](#)). The inhibitory effect of valproate on histone deacetylase, linked to Wnt signaling, which is involved in cell division, is a plausible mechanism by which teratogenic effects could develop.

Because alternative treatment strategies lacking teratogenic risk are available that can effectively manage

bipolar symptoms, valproate should generally be discontinued in patients who are trying to conceive, and if pregnancy occurs, valproate should not be reinstated until after the first trimester.

Cognitive effects of prenatal exposure to valproate have been found. When assessed at age 3 years, children who had experienced fetal exposure to valproate had IQ scores 6–9 points lower than those of children who had fetal exposure to lamotrigine, carbamazepine, or phenytoin ([Meador et al. 2009](#)).

## Breast Feeding

Valproate is minimally present in breast milk. [Piontek et al. \(2000\)](#) reported that among six mother–infant pairs, serum valproate levels in the infants ranged from 0.9% to 2.3% of the mother's serum levels, with absolute serum levels of 0.7–1.56 µg/mL. The valproate concentration in an infant was 1.5% of the maternal concentration ([Wisner and Perel 1998](#)).

## Overdose

Recovery from overdose-induced coma has occurred with serum valproate concentrations greater than 2,000 µg/mL. In addition, serum valproate concentrations have been reduced by hemodialysis and hemoperfusion, and valproate-induced coma has been reversed with naloxone ([Rimmer and Richens 1985](#)).

---

## Drug-Drug Interactions

---

Because valproate is highly protein bound and extensively metabolized by the liver, a number of potential interactions may occur with other protein-bound or extensively metabolized drugs ([Fogel 1988](#); [Rimmer and Richens 1985](#)). Thus, free fraction concentrations of valproate in serum can be increased, and valproate toxicity can be precipitated, by coadministration of other highly protein-bound drugs (e.g., aspirin) that can displace valproate from its protein-binding sites.

In the context of coadministration, valproate's competitive inhibition of lamotrigine excretion via glucuronidation requires that lamotrigine be started at a lower dosage—usually 25 mg every other day—with increases implemented cautiously. Lamotrigine's steady-state plasma concentrations are also generally lower when the drug is used with valproate, although not in all patients.

---

## Conclusion

---

Valproate's broad spectrum of efficacy in bipolar and related disorders and generally good tolerability make it a foundation of treatment for many patients with bipolar disorders. For optimal results, most patients should be treated with the formulation that permits once-daily dosing and has the lowest peak-to-trough serum level, which in the United States currently is divalproex ER. Although onset of action of valproate occurs quickly with use of loading-dose strategies, gradual dosage titration is the preferred method of treatment initiation for all but the most severe manic states. Medication tolerability is of paramount importance

in fostering patient adherence to long-term treatment regimens.

During maintenance treatment, it is often necessary to reduce the dosage if adverse effects persist. Valproate is principally effective in and prophylactic for manic symptoms, although its prophylactic benefits in depression are now relatively well established. A history of multiple affective episodes or a current presentation characterized by irritability may be a particularly strong indicator of a favorable response to valproate. Although some patients may achieve acute and sustained remission with valproate monotherapy, many patients are more effectively treated with combinations, including other mood stabilizers and adjunctive medications. All current medications with established or putative roles in bipolar disorder can be combined with valproate.

## CHAPTER 38

# Carbamazepine, Oxcarbazepine, and Licarbazepine

Po W. Wang, M.D.

Terence A. Ketter, M.D.

Robert M. Post, M.D.

**Pharmacotherapy** of bipolar disorders is complex and rapidly evolving. Antipsychotics, antidepressants, anxiolytics, and new-generation anticonvulsants are commonly combined with traditional first-line mood stabilizers (lithium, valproate, carbamazepine) in clinical settings ([American Psychiatric Association 2002](#); [Ketter 2005](#); [Suppes et al. 2005](#)). Clinicians are challenged with integrating complex data regarding efficacy and adverse-effect profiles with pharmacological properties in efforts to provide safe, effective, state-of-the-art pharmacotherapy for patients with bipolar disorder.

In this chapter we review the pharmacology of carbamazepine (CBZ) and its analog oxcarbazepine (OXC). In the past, CBZ was considered an alternative to lithium and valproate rather than a first-line intervention in the treatment of bipolar disorder ([American Psychiatric Association 2002](#)), largely owing to methodological limitations of early studies of efficacy in bipolar disorder, complexity of use due to adverse effects and drug-drug interactions, and lack of a U.S. Food and Drug Administration (FDA) indication for the treatment of bipolar disorder. CBZ received an indication for the treatment of acute manic and mixed episodes in bipolar disorder following evidence from two randomized double-blind, placebo-controlled, parallel-group studies in patients with bipolar disorder ([Weisler et al. 2004, 2005](#)). Importantly, in selected patients, CBZ and OXC may offer favorable efficacy and tolerability—in particular, less weight gain and metabolic problems—and thus can be important treatment alternatives ([Akiskal et al. 2005](#)). Likewise, the active monohydrate metabolite of OXC, licarbazepine, and its prodrug, eslicarbazepine acetate (ESL), may have improved tolerability, although evidence of efficacy in bipolar disorder is lacking.

---

## History and Discovery

---

As one of the first alternatives to lithium and first-generation antipsychotics to become available, CBZ has played an important role in the development of therapeutic interventions for bipolar disorder ([Post et al. 2007](#)). CBZ was developed in 1957 by J.R. Geigy AG in Europe, and its efficacy in epilepsy and paroxysmal pain was established by

the 1960s and in bipolar disorder by the early 1970s ([Takezaki and Hanaoka 1971](#)). In the 1970s, acute mania was managed primarily with lithium and first-generation antipsychotics. Lithium was dramatically effective in patients with classical euphoric mania but was less effective in patients with mixed or dysphoric mania, rapid cycling, a higher number of previous episodes, mood-incongruent delusions, or concurrent substance use disorders ([Ketter and Wang 2002](#)). Furthermore, the fact that starting treatment with lithium required a slow initial dosage titration meant that there was often a substantial delay before the medication's beneficial effects were experienced.

Limitations of lithium and first-generation antipsychotics led investigators to explore other treatment options for bipolar disorder. On the basis of early reports of favorable psychotropic profiles in patients with epilepsy and preliminary observations in mood disorders, systematic investigations of CBZ ([Ballenger and Post 1978](#)) and valproate commenced, and these anticonvulsants emerged as effective in acute mania. CBZ and valproate were used off-label for bipolar disorder in the 1980s and early 1990s, respectively. The CBZ analog OXC was anecdotally reported as useful in bipolar disorder in the 1980s ([Müller and Stoll 1984](#)), but it was not marketed in the United States for the treatment of epilepsy until 2000.

Because of economic concerns such as patent protection limitations and the high cost of obtaining FDA approval, a CBZ indication for bipolar disorder was not initially sought in the United States. A proprietary CBZ beaded extended-release capsule formulation (Equetro) received an FDA indication for the treatment of acute manic and mixed episodes in patients with bipolar disorder in late 2004.

OXC was approved for the treatment of epilepsy in the United States in 2000, following the development of several new anticonvulsants in the 1990s. The new anticonvulsants have heterogeneous psychotropic profiles ([Ketter et al. 2003](#)), with only the older drug phenytoin ([Mishory et al. 2000](#)) and OXC ([Emrich 1990](#)) appearing effective thus far in (albeit small) controlled trials in acute mania and lamotrigine in the acute treatment and maintenance treatment of bipolar depression. As with CBZ, economic concerns such as patent protection limitations and the high cost of obtaining FDA approval are substantial barriers to seeking an OXC acute mania indication in the United States. On the basis of its greater ease of use, some clinicians consider OXC to be an alternative to CBZ ([American Psychiatric Association 2002](#)). However, use of OXC remains limited by the lack of adequate data supporting its efficacy in bipolar disorder.

Licarbazepine, the active monohydroxy metabolite of OXC, was initially assessed by Novartis for treatment of acute mania rather than epilepsy. As of 2015, the three randomized controlled trials of licarbazepine in acute mania (on [clinicaltrials.gov](http://clinicaltrials.gov)) had not yet been published. In 2009, the European Medicines Agency approved ESL, a prodrug for the *S*-enantiomer of licarbazepine (Zebinix; BIAL-Portela and Ca, S.A.), for the treatment of epilepsy. In 2013, the FDA approved ESL (Aptiom, submitted by Sunovion, under license from BIAL-Portela and Ca, S.A.) for epilepsy. Although ESL may have greater tolerability than CBZ and does not carry black box warnings, its efficacy in acute mania has not been established ([Grunze et al. 2015](#)).

---

## Structure-Activity Relationships

---

CBZ is an iminostilbine derivative with a dibenzazepine nucleus. CBZ's carbamyl (carboxamide) group at position 5 appears to be associated with substantial anticonvulsant effects. Like imipramine, CBZ has a tricyclic structure; however, whereas

imipramine has a 5-aryl substituent, CBZ has a 5-carboxamide substituent, and this structural difference is thought to mediate CBZ's markedly different effects compared with imipramine, as described later (see "Mechanisms of Action" section). OXC differs structurally from CBZ only in that it has a ketone substitution at the 10,11-position, and (as noted below) the bulk of the evidence thus far suggests that this structural similarity is paralleled by mechanistic similarity. ESL, like OXC, has a stabilizing subgroup at the 10,11-position (an acetoxymethyl side chain) and is metabolized to the *S*-isomer of the common metabolite of OXC, licarbazepine ([Almeida and Soares-da-Silva 2007](#)).

---

## Pharmacological Profiles

---

CBZ and OXC have preclinical anticonvulsant profiles similar to that of phenytoin and less broad than that of valproate or lamotrigine. CBZ and OXC, like phenytoin, valproate, and lamotrigine, are effective in the maximal electroshock model of generalized tonic and/or clonic seizures and in blocking seizures resulting from amygdala kindling (a model of partial seizures). CBZ and OXC, like phenytoin but unlike valproate and lamotrigine, are not effective in the pentylenetetrazole model of absence seizures and, like phenytoin and lamotrigine but unlike valproate, fail to block kindling development (a model of epileptogenesis).

As expected from their preclinical profiles, CBZ and OXC, like phenytoin, valproate, and lamotrigine, are effective in partial seizures with and without secondary generalization and, like phenytoin but unlike valproate and lamotrigine, are ineffective in absence seizures. CBZ and OXC also have analgesic effects in paroxysmal pain syndromes and thus are effective in trigeminal neuralgia.

ESL, which shares a common active metabolite with OXC, has a similar preclinical anticonvulsant profile. Thus, ESL, like OXC, is effective in the maximal electroshock model of generalized tonic and/or clonic seizures and effective in blocking seizures resulting from amygdala kindling ([Almeida and Soares-da-Silva 2007](#)).

---

## Pharmacokinetics and Disposition

---

### Carbamazepine

CBZ is available in the United States as a proprietary product (Tegretol; Novartis Pharmaceuticals Corporation) supplied as a 100 mg/5 mL suspension; 100-mg chewable tablets; 200-mg tablets; and 100-, 200-, and 400-mg extended-release (Tegretol-XR) tablets ([Physicians' Desk Reference 2015](#)). An additional proprietary beaded extended-release capsule formulation—Carbatrol (Shire US Inc.), marketed for epilepsy, and Equetro (Validus Pharmaceuticals), marketed for bipolar disorder—is supplied in 100-, 200-, and 300-mg strengths ([Physicians' Desk Reference 2015](#)). Intramuscular and depot formulations are not available. CBZ is also available in generic formulations.

CBZ is extensively metabolized, with only about 3% being excreted unchanged in the urine. The main metabolic pathway of CBZ (to its active 10,11-epoxide, CBZ-E) appears to be primarily via cytochrome P450 (CYP) 3A4/5 ([Figure 38-1](#), top), with a minor contribution by CYP2C8 ([Kerr et al. 1994](#)). This epoxide pathway accounts for about 40% of CBZ disposition, and an even greater percentage in patients with induced epoxide

pathway metabolism (Faigle and Feldmann 1995). The frequency distribution of CBZ kinetic parameters is unimodal, consistent with CYP3A3/4 being the crucial isoform. With enzyme induction (of the epoxide pathway, presumably via CYP3A3/4 induction), formation of CBZ-E triples, and thus the CBZ-E/CBZ ratio increases (Eichelbaum et al. 1985). Other pathways include aromatic hydroxylation (25%), which is apparently via CYP1A2 and is not induced concurrently with epoxide formation, and glucuronide conjugation of the carbamoyl side chain (15%) by uridine diphosphoglucuronosyltransferase (UGT), presumably primarily by UGT2B7 (Staines et al. 2004). These other pathways yield inactive metabolites.

**FIGURE 38-1.** Carbamazepine and oxcarbazepine metabolism.

Note. +=enzyme induction; -=enzyme inhibition; CBZ=carbamazepine; CBZ-E=carbamazepine-10,11-epoxide; CBZ-D=carbamazepine-10,11-dihydro-dihydroxide; OXC=oxcarbazepine; MHD=monohydroxy derivative; CYP3A3/4=cytochrome P450 3A3/4 isoenzyme.

CBZ has erratic absorption and a bioavailability of about 80%. Tablets should not be exposed to humidity, because moisture can cause solidification and decrease the drug's bioavailability (Nightingale 1990). CBZ is about 75% bound to plasma proteins and has a moderate volume of distribution of about 1 L/kg. Before autoinduction of the epoxide pathway, the half-life of CBZ is about 24 hours, and clearance is about 25 mL/min. However, after autoinduction (2–4 weeks into therapy), the half-life falls to about 8 hours, and clearance rises to about 75 mL/min. This may require dosage adjustment to maintain adequate blood concentrations and therapeutic effects. The active CBZ-E metabolite has a half-life of about 6 hours and is converted to an inactive diol (CBZ-D) by epoxide hydrolase. The extended-release CBZ formulations given twice daily yield steady-state CBZ concentrations similar to those seen with the immediate-release formulation given four times daily (Garnett et al. 1998; Thakker et al. 1992).

When CBZ is used in the treatment of acute mania, two divergent clinical needs influence the rate of dosage titration. The need for rapid control of the manic syndrome should be balanced against the need to minimize adverse effects (which can be worsened with overly aggressive escalation of CBZ dosage). Thus, although a loading-dose strategy may be tolerated and effective in the treatment of mania with valproate (Keck et al. 1993), the potential for neurotoxic adverse effects (i.e., CNS symptoms such as dizziness, somnolence, cognitive slowness, tremors, ataxia, and slurred speech) limits the use of such an approach with CBZ.

Nonetheless, in the inpatient therapy of mania, CBZ is commonly started at 400–800 mg/day in divided doses and increased as tolerated (by 200 mg/day every 1–4 days) to provide clinical efficacy. In controlled studies, the beaded extended-release capsule formulation was started at 200 mg twice per day and increased daily by 200 mg to a final dosage as high as 1,600 mg/day (Weisler et al. 2004, 2005). Managing dosage titration against adverse effects is more important than targeting a specific blood concentration range. The usual dosage range is 800–1,600 mg/day given in up to three or four divided doses with the immediate-release formulation. Sustained-release formulations permit two divided doses per day and may even allow most or all of the daily dosage to be taken at bedtime in mood disorder patients. Although this strategy is convenient, it may not be feasible in some individuals because of neurotoxicity at the peak serum concentration, which occurs about 4–8 hours after ingesting a dose. CBZ has a fairly rapid onset of antimanic efficacy. Thus, if clinical improvement has not occurred after 7–10 days, the clinician should consider augmentation or alternative strategies.

In a 6-month open-label extension of controlled studies in acute mania, beaded extended-release capsule CBZ was started at 200 mg twice per day and increased by 200 mg every 3 days (versus every day in the acute studies) to a final dosage as high as 1,600 mg/day (Ketter et al. 2004). This approach decreased the incidence of central nervous system (CNS; dizziness, somnolence, ataxia), digestive system (nausea, vomiting), and dermatological (pruritus) adverse effects by about 50%.

In less acute situations, CBZ is often started at 100–200 mg/day and increased as necessary and tolerated by 200 mg/day every 4–7 days. Even more gradual initiation strategies may be necessary to alleviate adverse effects. Thus, starting with 50 mg (half of a chewable 100-mg tablet) at bedtime and increasing by 50 mg every few days can result in a better-tolerated initiation. Often, initial dosages of CBZ may be better tolerated after 1 month of therapy, once autoinduction of CBZ metabolism has decreased the serum CBZ concentrations (Cereghino 1975) and accommodation and tolerance to adverse effects such as sedation have occurred. In two CBZ-versus-lithium maintenance studies, trough serum CBZ concentrations were maintained at 4–12 µg/mL, with a mean of 6.4 µg/mL (Greil et al. 1997) and 7.7 µg/mL (Denicoff et al. 1997).

Because CBZ dosage and serum and cerebrospinal fluid (CSF) concentrations do not correlate with its psychotropic efficacy (Post 1989; Post et al. 1983, 1984a), clinical management involves gradual up-titration of CBZ dosages until adequate therapeutic efficacy is achieved, adverse effects supervene, or serum concentrations exceed 12 µg/mL. The 4–12 µg/mL serum CBZ concentration range used in epilepsy may be considered as a broad target, with CBZ serum concentrations used as checks for pharmacokinetic problems. The active CBZ-E metabolite can yield therapeutic and adverse effects similar to those of CBZ, but it is not detected in conventional CBZ assays. Thus, the unwary clinician may misinterpret the significance of therapeutic or adverse effects associated with low or moderate serum CBZ concentrations.

In responders, a dose-response relationship may be evident, so slowly increasing CBZ dosages to maximize response in the absence of significant adverse effects would be an appropriate clinical strategy. However, if there is no hint of therapeutic response at moderate dosages, it is unlikely that pushing to very high dosages would be beneficial.

## Oxcarbazepine

OXC is available in the United States as a proprietary product (Trileptal; Novartis Pharmaceuticals Corporation) supplied as a 300 mg/5 mL suspension and as 150-, 300-, and 600-mg tablets ([Physicians' Desk Reference 2015](#)). A novel once-daily extended-release formulation of OXC (Oxtellar XR; Supernus Pharmaceuticals Inc.) has also been approved for the adjunctive treatment of partial seizures in adults and in children ages 6–17 years. Limited data suggest that this formulation has enhanced tolerability ([Chung et al. 2016](#)). Intramuscular and depot formulations of OXC are not available.

OXC is 96% absorbed, and the modest effect of food on OXC kinetics does not appear to be of therapeutic consequence ([Degen et al. 1994](#)). OXC is 60% bound to plasma proteins. Like CBZ, OXC has a complex metabolism ([Figure 38-1](#), bottom). Thus, OXC is rapidly reduced to an active monohydroxy derivative (MHD) by cytosol arylketone reductase. The MHD form (also called licarbazepine) is 40% bound to plasma proteins, has a moderate volume of distribution of about 0.8 L/kg, and has a half-life of about 9 hours. OXC is eliminated primarily in the form of MHD (70%) and MHD glucuronide conjugates (20%), with a small proportion (10%) eliminated in the form of OXC glucuronide conjugates and CBZ-D. OXC does not cause autoinduction, and it causes substantially less heteroinduction than does CBZ. Thus, as described later in this chapter (see section “Drug-Drug Interactions”), medication interactions are less problematic with OXC than with CBZ ([Baruzzi et al. 1994](#)).

OXC is started at 150 mg/day and increased every other day by 150 mg to a target of 1,200–1,600 mg/day in two to three divided doses. Further dosage increases up to 2,400 mg/day may be clinically indicated. In small trials of OXC in acute mania, mean OXC dosages were 1,400–2,400 mg/day ([Emrich 1990](#); [Emrich et al. 1983](#)). As with CBZ, when used to treat patients with bipolar disorder, OXC is titrated to the desired clinical effect as tolerated, with the serum concentration range used in epilepsy considered as a broad target, and with OXC serum concentrations used as a check for pharmacokinetic problems. Equipotent doses of OXC range from 1.2 to 1.5 times the CBZ dose.

## Eslicarbazepine Acetate

ESL is available in the United States as a proprietary product (Aptiom; Sunovion Pharmaceuticals Corporation) supplied in 200-, 400-, 600-, and 800-mg tablets ([Physicians' Desk Reference 2015](#)). Extended-release, intramuscular, and depot formulations are not available.

Licarbazepine is the active MHD product of OXC, and eslicarbazepine is the *S*-isomer of licarbazepine ([Figure 38-2](#)). ESL is a prodrug of eslicarbazepine. Licarbazepine is 40% bound to plasma proteins, has a moderate volume of distribution (about 0.8 L/kg), and has a half-life of about 20–24 hours ([Zaccara et al. 2015](#)). Elimination is mainly through the kidneys, unchanged or glucuronidated ([Zaccara et al. 2015](#)). ESL pharmacokinetics do not appear to be affected in patients with moderate hepatic impairment ([Almeida et al. 2008](#)).

**FIGURE 38-2.** Oxcarbazepine and eslicarbazepine acetate (ESL) metabolism.

Oxcarbazepine is metabolized to the active monohydroxy derivative as a racemic mixture with a higher (4:1) ratio of the *S*-enantiomer compared with the *R*-enantiomer. ESL is rapidly metabolized to the common but specifically *S*-enantiomer of the monohydroxy derivative (Bialer 2006).

In a recent study evaluating the safety of two dosage-titration regimens of ESL in the treatment of bipolar I patients with acute mania, ESL was started at 600 mg/day or 800 mg/day and increased every 3 days by 600 mg or 800 mg to a target dosage of 1,800 mg/day or 2,400 mg/day, respectively. Despite the aggressive titration schedule, adverse effects were of mostly mild to moderate intensity (Grunze et al. 2015).

Transitioning a patient from OXC to ESL would be expected to be relatively straightforward, with an OXC:ESL dose ratio of 1:1, and could occur within 1 day. By contrast, transitioning a patient from CBZ to ESL would be considerably more complicated, with a CBZ:ESL dose ratio of 1:1.3, and would require at least 1-2 weeks, as clinically determined (Peltola et al. 2015).

## Mechanisms of Action

CBZ and OXC have both structural and mechanistic similarities. However, these agents have such a diversity of biochemical effects that linking these mechanisms to their varying clinical actions presents a considerable challenge.

## Carbamazepine

Although CBZ has a tricyclic structure like that of imipramine, the two agents have markedly different neurochemical, hepatic, and clinical effects. CBZ lacks imipramine's major effects on monoamine reuptake and high affinity for histaminergic, cholinergic, adrenergic  $\beta$ , and dopamine receptors. However, CBZ has a wide range of other cellular and intracellular effects.

One useful way of considering CBZ's diverse mechanisms is from the perspective of onset of action ([Post 1988](#)). CBZ cellular actions with acute onset that might parallel the time course of clinical anticonvulsant effects include decreasing sodium influx and glutamate release, increasing potassium conductance, and interacting with peripheral benzodiazepine and  $\alpha_2$ -adrenergic receptors. Acute or subchronic actions—such as increasing striatal cholinergic neurotransmission; decreasing adenylate cyclase activity stimulated by dopamine, norepinephrine, and serotonin; and decreasing turnover of dopamine, norepinephrine, and  $\gamma$ -aminobutyric acid (GABA)—may be pertinent to CBZ's clinical antimanic effects. Finally, the actions requiring chronic administration—include increasing serum and urinary free cortisol, free tryptophan, substance P sensitivity, and adenosine A<sub>1</sub> receptors and decreasing cerebrospinal somatostatin—may be those that are most closely related to CBZ's clinical antidepressant effects.

## Oxcarbazepine

Compared with the knowledge base on CBZ's mechanisms of action, less is known about OXC (and thus ESL, given their common active molecules). Most evidence thus far suggests that OXC's structural similarity to CBZ is paralleled by mechanistic similarity ([Ambrósio et al. 2002](#)). For example, OXC, like CBZ, appears to decrease sodium ([Benes et al. 1999](#); [Wamil et al. 1994](#)) and calcium ([Stefani et al. 1995](#)) influx, glutamate release ([Ambrósio et al. 2001](#)), and serum thyroxine concentrations ([Isojärvi et al. 2001b](#)); to increase potassium conductance ([McLean et al. 1994](#)) and dopaminergic ([Joca et al. 2000](#)) neurotransmission; and to block adenosine A<sub>1</sub> receptors ([Deckert et al. 1993](#)). However, there may be some mechanistic dissimilarities, particularly given the marked difference between OXC and CBZ in degree of hepatic enzyme induction. For example, OXC appears to be a less potent modulator of voltage-gated calcium channels than is CBZ ([Schmutz et al. 1994](#); [Stefani et al. 1997](#)). The general OXC-CBZ mechanistic overlap is consistent with the hypothesis that OXC and CBZ have similar effects in bipolar disorder, which in turn is consistent with preliminary clinical observations; however, these similarities remain to be established in large controlled clinical studies.

## Eslicarbazepine Acetate

ESL and OXC likely have a similar mode of action because they share the same main active metabolite, licarbazepine (although the oxcarbazepine metabolite is racemic licarbazepine, whereas the ESL metabolite is exclusively the *S*-isomer of licarbazepine) ([Almeida and Soares-da-Silva 2007](#); [Schütz et al. 1986](#)). Thus, ESL behaves as a blocker of the voltage-gated sodium channel (VGSC; [Almeida and Soares-da-Silva 2007](#)). However, whereas ESL reduces VGSC availability through enhancement of slow inactivation, CBZ acts by altering fast inactivation of VGSC ([Hebeisen et al. 2015](#)). Eslicarbazepine and CBZ also differ with regard to submaximal GABA currents, Kv7.2 outward currents, and high- and low-affinity Cav3.2 inward currents ([Keating 2014](#)). OXC and ESL may have some mechanistic differences as well, with CBZ and OXC enhancing excitatory synaptic

transmission via antagonism of the adenosine A<sub>1</sub> receptor at therapeutic doses, whereas ESL does so only at supratherapeutic high dosages (Booker et al. 2015).

## Indications and Efficacy

### Seizure Disorders and Trigeminal Neuralgia

In the United States, CBZ is approved as monotherapy for the treatment of trigeminal neuralgia and complex partial, generalized tonic-clonic, and mixed seizure disorders (Physicians' Desk Reference 2015). OXC is approved for the treatment of partial seizures as monotherapy in adults and as adjunctive therapy in adults and children older than 4 years (Physicians' Desk Reference 2015). ESL is approved by the FDA as monotherapy or adjunctive treatment for partial-onset seizures (Physicians' Desk Reference 2015).

CBZ and OXC appear to have overlapping anticonvulsant effects, with similar efficacy in newly diagnosed epilepsy patients (Dam et al. 1989). However, there may be dissimilarities. For example, switching to OXC may be effective in patients with inadequate response or intolerable adverse effects with CBZ (Beydoun et al. 2000; Van Parys and Meinardi 1994), and adding OXC may improve efficacy in patients with inadequate response to CBZ (Barcs et al. 2000; Glauser et al. 2000).

### Acute Mania

The FDA approved a proprietary CBZ beaded extended-release capsule formulation (Equetro) for the treatment of acute manic and mixed episodes in patients with bipolar disorder in late 2004, but CBZ and OXC are still considered alternative agents in the management of bipolar disorder (American Psychiatric Association 2002). Twenty-six controlled studies have investigated the efficacy of CBZ, OXC, and ESL in acute mania (summarized in Table 38-1). In these studies, there is more compelling evidence for the efficacy of CBZ (18 studies encompassing 594 patients receiving CBZ) than for the efficacy of OXC (5 studies including 119 patients receiving OXC) or ESL (2 studies encompassing 146 patients receiving ESL).

## Carbamazepine and Oxcarbazepine

Two trials that found a proprietary CBZ beaded extended-release capsule formulation (Equetro) superior to placebo are of particular interest because they used a randomized double-blind, placebo-controlled design (Weisler et al. 2004, 2005) and led to the FDA indication for the treatment of acute manic and mixed episodes in patients with bipolar disorder. These reports are consistent with multiple earlier studies using placebo-drug-placebo, active comparator (lithium or first-generation antipsychotics), and adjunctive (compared with placebo, lithium, or first-generation antipsychotics added to lithium or antipsychotics) designs. Thus, across studies using diverse paradigms (see Table 38-1), overall antimanic response rates with CBZ were generally comparable to those seen with lithium or first-generation antipsychotics, or in other studies with valproate (Ketter 2010). Taken together, this collection of clinical trials provides substantial evidence for the acute antimanic efficacy of CBZ and preliminary evidence for the acute antimanic efficacy of OXC. For CBZ, this current body of existing data appears greater than that initially utilized by the FDA to approve lithium for the treatment of acute mania.

For CBZ, improvement appears to occur across the entire manic syndrome and does not seem to be due to nonspecific sedative properties because patients often show dramatic clinical improvement in the absence of marked sedation. Because CBZ and OXC are frequently used in combination with other medications in the acute treatment of mania, knowledge of CBZ's extensive and OXC's more limited drug-drug interactions (as described in the later section with that title) is often required to achieve optimal outcomes.

## Eslicarbazepine Acetate

In two 3-week studies of ESL in acute mania, ESL did not separate from placebo on the primary outcome measure of Young Mania Rating Scale change; however, Global Clinical Impression changes were suggestive of efficacy in one of the two studies (Grunze et al. 2015). High rates of placebo response and poor study recruitment (leading to premature study termination) may have contributed to failure in the second study (Grunze et al. 2015).

## Acute Depression

Limited controlled data exist regarding the acute antidepressant effects of CBZ, and there are no published controlled studies of the antidepressant effects of OXC or ESL (Table 38-2). Although CBZ appears to have weaker antidepressant than antimanic properties, some evidence suggests that it may provide antidepressant benefit in about one-third of patients with treatment-resistant depression (Neumann et al. 1984; Post et al. 1986; Small 1990), whereas in a Chinese study, CBZ produced a response rate closer to two-thirds in patients with non-treatment-resistant depression (Zhang et al. 2007). Unfortunately, most of these studies are limited by their use of small samples of heterogeneous (both bipolar and unipolar) patients with highly treatment-resistant depression.

## Maintenance and Relapse-Prevention Treatment

### Carbamazepine and Oxcarbazepine

A series of 18 double-blind randomized, open randomized, or otherwise partially controlled studies have examined the efficacy of CBZ and OXC in maintenance treatment of bipolar disorder (summarized in Table 38-3). The 15 CBZ trials are consistent with a very substantial open literature suggesting that CBZ may be effective in preventing mood episodes when administered during long-term treatment, either alone or in combination with lithium in previous lithium nonresponders (see Table 38-3). Indeed, five reviews of different subsets of studies included in Table 38-3 broadly indicated that CBZ and lithium monotherapy had comparable prophylactic effects in patients with bipolar disorder (Ceron-Litvoc et al. 2009; Dardennes et al. 1995; Davis et al. 1999; Hirschfeld and Kasper 2004; Smith et al. 2007). CBZ may have equal *prophylactic* antidepressant and antimanic efficacy, in contrast to its less potent *acute* antidepressant compared with antimanic effects. In contrast, data regarding the efficacy of OXC in preventing new mood episodes in patients with bipolar disorder are more limited (Cabrera et al. 1986; Vieta et al. 2008; Wildgrube 1990). A 2008 Cochrane review assessed the available data as inadequate to recommend OXC in the maintenance treatment of bipolar disorder (Vasudev et al. 2008).

In one study, the overall analysis suggested that maintenance treatment was more effective with lithium than with CBZ (Greil et al. 1997). However, subgroup differences may exist, such that lithium may be more effective in patients with “classical” bipolar disorder (i.e., bipolar I disorder with no mood-incongruent delusions or comorbidity), whereas CBZ may be more effective in patients with “nonclassical” bipolar disorder (e.g., bipolar II disorder, DSM-IV [American Psychiatric Association 1994] bipolar disorder not otherwise specified, bipolar disorder with mood-incongruent delusions or comorbidity) (Greil et al. 1998).

In another study, lithium maintenance treatment appeared to be more effective than CBZ in patients with no more than 6 months’ prior exposure to either agent (Hartong et al. 2003). However, this advantage was offset by more early discontinuations in the lithium group, so that similar proportions (about one-third) of patients completed 2 years with no episode. Patients taking lithium versus CBZ tended to have somewhat greater risk of episodes in the first 3 months and markedly less risk of episodes after the first 3 months, with a recurrence risk of only 10% per year with lithium after the first 3 months. Patients taking CBZ had a more consistent rate of relapse or recurrence of about 40% per year.

Some CBZ relapse-prevention trials have been criticized for their methodological limitations (Murphy et al. 1989), although such difficulties are common in maintenance studies. (For example, divalproex and lithium failed to separate from placebo on the primary efficacy measure in a 1-year maintenance study [Bowden et al. 2000], a result at least partially due to methodological problems.) Taken together, this collection of randomized placebo-controlled, placebo-drug-placebo, and lithium comparator studies and trials in rapid-cycling and lithium-resistant populations provides substantial evidence for the preventive efficacy of CBZ (Priem and Gelenberg 1989). CBZ may be effective in some individuals with valproate-resistant illness (Post et al. 1984b), and the CBZ-plus-valproate combination may be effective in patients with little or no response to either agent alone (Keck et al. 1992; Ketter et al. 1992).

In a retrospective study, although 22 of 34 (65%) patients with treatment-resistant bipolar disorder responded to primarily adjunctive open CBZ acutely, when patients were

assessed 3–4 years later, only 7 of 34 (21%) and 2 of 34 (6%) were considered probable and clear responders, respectively ([Frankenburg et al. 1988](#)). [Post et al. \(1990; Post and Weiss 2011\)](#) have suggested that loss of CBZ prophylactic efficacy over time may be related to a unique form of contingent tolerance. In these instances, techniques such as switching to another treatment regimen with a different mechanism of action or returning later to CBZ (after a period of not taking CBZ) are worth considering, based on case reports and anecdotal observations.

### Eslicarbazepine Acetate

A 6-month continuation study investigated the efficacy of three different dosages of ESL (300 mg/day, 900 mg/day, and 1,800 mg/day) in preventing symptom recurrence in the bipolar patients who had participated in the earlier placebo-controlled studies of ESL in acute mania. Of the 85 patients who had responded during acute treatment and were randomly assigned to one of the three dosage groups, at least 50% did not show any clinical worsening, although there was no significant difference between dosage groups ([Grunze et al. 2015](#)).

## Response Predictors

Predictors of CBZ and OXC response have not been adequately elucidated. CBZ can be effective in patients with a history of lithium unresponsiveness or intolerance ([Okuma et al. 1979; Post et al. 1987](#)). Nonclassical bipolar disorder ([Greil et al. 1998; Small et al. 1991](#)) and stable or decreasing episode frequency ([Post et al. 1990](#)) may be associated with CBZ response. Patients with a history of affective illness in first-degree relatives may preferentially respond to lithium, whereas the converse may be the case for CBZ ([Ballenger and Post 1978; Post et al. 1987](#)). Patients with comorbid neurological or substance abuse problems and inadequate lithium responses may respond to CBZ or valproate ([Himmelhoch 1987; Himmelhoch and Garfinkel 1986](#)). Preliminary observations indicate that baseline cerebral (left insula) hypermetabolism may be a marker of CBZ response ([Ketter et al. 1999](#)).

Reports vary with respect to the relationships between CBZ response and dysphoric manic presentations ([Lusznat et al. 1988; Post et al. 1989](#)) and illness severity ([Post et al. 1987; Small et al. 1991](#)). Antidepressant responses to CBZ may be seen in patients with more severe depression, more discrete depressive episodes, less chronicity, and greater decreases in serum thyroxine concentrations with CBZ ([Post et al. 1986, 1991](#)).

Although the initial studies of [Post et al. \(1987\)](#) and [Okuma et al. \(1981; Okuma 1983\)](#) indicated that some rapid-cycling patients were responsive to CBZ, other investigators found less robust results ([Dilsaver et al. 1993; Joyce 1988](#)). As with lithium, later studies by Okuma and associates reported a lower CBZ maintenance response rate in rapid cycling compared with non-rapid-cycling illness ([Okuma 1993](#)). However, even these rapid-cycling patients had a CBZ response rate (40%) that was higher than rates reported with other agents in other studies. [Denicoff et al. \(1997\)](#) also observed that patients with a history of rapid cycling had a lower response rate to maintenance CBZ (as with maintenance lithium) compared with those without such as history (19% vs. 54%), but rapid cyclers did well on the combination of lithium and CBZ.

---

## Side Effects and Toxicology

---

Baseline evaluation of patients with bipolar disorder includes not only psychosocial assessment but also a general medical evaluation in view of the risk of medical processes, which could confound diagnosis or influence management decisions, and the risk of adverse effects, which may occur with treatment. Assessment commonly includes history; physical examination; complete blood count with differential and platelets; renal, hepatic, and thyroid function; toxicology; pregnancy tests; and other chemistries and electrocardiogram as clinically indicated ([American Psychiatric Association 2002](#)). Such evaluation provides baseline values for parameters that influence decisions about choice of medication and intensity of clinical and laboratory monitoring.

## Carbamazepine

Adverse effects appear to have substantial impact on the utility of CBZ in the treatment of bipolar disorder. In a pooled analysis of two multicenter acute mania FDA registration studies of a proprietary extended-release capsule formulation of carbamazepine (Equetro), the number needed to harm for somnolence was 6, and for at least 7% weight gain, the number was 23 ([Ketter et al. 2011](#)), suggesting that neurocognitive adverse effects more than weight gain might limit CBZ utility ([Ketter 2015](#)). Some patients may tolerate CBZ better than other agents, particularly during longer-term treatment, because CBZ appears to have a low propensity to cause adverse effects such as weight gain and metabolic disturbance that can limit the utility of some other agents ([Akiskal et al. 2005](#); [Ketter 2015](#)).

CBZ has several common dose-related adverse effects that generally can be minimized by attention to drug-drug interactions and gradual titration of dosage or reversed by decreasing dosage. At high dosages, patients can develop neurotoxicity with sedation, ataxia, diplopia, and nystagmus, particularly early in therapy, before the autoinduction process is complete and tolerance develops to the CNS adverse effects of CBZ. Because there is wide interindividual variation in susceptibility to adverse effects at any given concentration, it is most useful clinically to titrate doses against each patient's adverse effects rather than targeting a fixed dosage or serum concentration range.

Neurotoxic effects that emerge 1–2 hours after an individual dose often signal that the adverse-effect threshold has been exceeded and that dose redistribution (spreading out the doses or giving more of the dose at bedtime) or dosage reduction may be required. Use of extended-release formulations may attenuate CBZ peak serum concentrations, enhancing tolerability.

CBZ commonly causes benign hematological (leukopenia, thrombocytopenia), dermatological (rash), electrolyte (asymptomatic hyponatremia), and hepatic (transaminase elevations) problems. Analogous serious problems are much less common. For example, mild leukopenia and benign rash occur in up to 1 in 10 patients, with the slight possibility that these usually benign phenomena are heralding malignant aplastic anemia and Stevens-Johnson syndrome, seen in about 1 in 100,000 patients ([Kramlinger et al. 1994](#); [Tohen et al. 1995](#)).

In view of the risk of rare but serious decreases in blood counts, which warrant a black box warning in the CBZ prescribing information, it is important to alert patients to seek immediate medical evaluation if they develop signs and symptoms of possible hematological reactions, such as fever, sore throat, oral ulcers, petechiae, and easy bruising or bleeding. Hematological monitoring needs to be intensified in patients with low or marginal leukocyte counts, and CBZ is generally discontinued if the leukocyte count falls below 3,000/ $\mu$ L or the granulocyte count below 1,000/ $\mu$ L. In the instance of benign

leukopenia, the addition of lithium can increase the neutrophil count back toward normal ([Kramlinger and Post 1990](#)), but this strategy is not likely to be helpful for the suppression of red cells or platelets, which is likely to indicate a more problematic process.

Serious rash may occur in about 1 in 100,000 patients. The risk of serious and sometimes fatal dermatological reactions, including toxic epidermal necrolysis and Stevens-Johnson syndrome, may be increased tenfold in certain Asian populations and has been strongly linked to the human leukocyte antigen (HLA) *B\*1502* allele ([Physicians' Desk Reference 2015](#)). Thus, the U.S. prescribing information includes a black box warning that individuals of Asian ancestry should be genetically tested for *HLA-B\*1502* and that carriers of this allele should not be treated with CBZ. A twelvefold increased risk of drug-induced hypersensitivity syndrome (DIHS; also called drug rash with eosinophilia and systemic symptoms [DRESS]) has also been linked to *HLA-A\*3101* in whites of northern European descent ([McCormack et al. 2011](#)). Given the risk of serious rash, patients should be alerted to seek medical attention immediately if a rash develops. In particular, rash in patients presenting with systemic illness or involvement of the eyes, mouth, or bladder (dysuria) constitutes a medical emergency: carbamazepine should be immediately discontinued, and the patient should be assessed emergently ([Scaparrotta et al. 2011](#)). For more benign presentations, CBZ is generally discontinued, because there is little ability to predict which cases will progress to more severe, potentially life-threatening problems. However, in rare instances of resistance to all medications except CBZ, a repeat trial of CBZ with a course of prednisone has usually been well tolerated ([Murphy et al. 1991](#); [Vick 1983](#)). A substantial number of patients with CBZ-induced rash may not develop a rash on reexposure (even without prednisone coverage), but if a rash develops again, it usually appears more rapidly than the first occurrence. Only 25%–30% of patients who develop a rash with CBZ also develop a rash (cross-sensitivity) with OXC.

CBZ, in common with multiple other anticonvulsant medications (including OXC and ESL), may increase the risk of suicidality, including suicidal behavior or ideation. Data from controlled trials of anticonvulsant medications compared with placebo found a 1.5-fold increased risk from 0.57% to 0.85% for psychiatric patients ([Physicians' Desk Reference 2015](#)).

Because of the risk of rare hepatitis, patients should be advised to seek medical evaluation immediately if they develop malaise or abdominal pain or other marked gastrointestinal symptoms. In general, CBZ (like other anticonvulsants) should be discontinued if liver function values exceed three times the upper limit of the normal range ([Martínez et al. 1993](#)).

CBZ may affect cardiac conduction and should be used with caution in patients with cardiac disorders such as heart block. A baseline electrocardiogram is worth considering if there is a positive cardiac history.

Conservative laboratory monitoring during CBZ therapy includes baseline studies and evaluation of complete blood count, differential, platelets, and hepatic indices initially and at 2, 4, 6, and 8 weeks and then every 3 months ([American Psychiatric Association 1994, 2002](#)). Most of the serious hematological reactions occur within the first 3 months of therapy ([Tohen et al. 1995](#)). In contemporary clinical practice, clinically indicated monitoring (e.g., when a patient becomes ill with a fever) is emphasized over scheduled monitoring. Patients who have abnormal or marginal indices at any point merit careful scheduled and clinically indicated monitoring. The U.S. prescribing information for the beaded extended-release capsule CBZ formulation recommends a baseline complete blood count including platelets, possibly reticulocytes, possibly serum iron, and hepatic function tests; closely monitoring patients with low or decreased white blood cell counts or

platelets; and considering discontinuation of CBZ if evidence indicates bone marrow depression ([Physicians' Desk Reference 2015](#)). Serum CBZ concentrations are typically assessed at steady state and then as indicated by inefficacy or adverse effects. An important clinical note is that because of autoinduction, CBZ concentrations may decrease during the first 2–3 weeks after treatment initiation ([Eichelbaum et al. 1975](#)), thus potentially requiring readjustment of steady-state dosing.

Dividing or reducing dosages, rescheduling individual doses in relation to mealtimes, and changing formulations can attenuate CBZ-induced gastrointestinal disturbance. The CBZ oral suspension formulation may have more proximal absorption and thus may exacerbate upper gastrointestinal adverse effects (nausea and vomiting) or attenuate lower gastrointestinal effects (diarrhea). The reverse holds for extended-release preparations.

Weight gain and obesity are important clinical concerns in the management of bipolar disorder. Medications and the hyperphagia, hypersomnia, and anergy commonly seen in bipolar depression can contribute to this important obstacle to optimal outcomes. CBZ is less likely than lithium ([Coxhead et al. 1992](#); [Denicoff et al. 1997](#)) or valproate ([Mattson et al. 1992](#)) to cause weight gain. In one study, CBZ caused weight gain in depressed (but not manic) patients, which seemed to be related to the degree of relief of depression ([Joffe et al. 1986](#)). Nevertheless, in view of its relatively benign effect on weight, CBZ may provide an important alternative to other mood stabilizers for patients who struggle with weight gain and obesity.

CBZ can induce hyponatremia, which may be tolerated well by some younger patients but can be particularly problematic in the elderly. If confusion develops in an elderly patient, serum sodium should be assessed. In rare instances, water intoxication and seizures can occur. In some cases, hyponatremia can be effectively counteracted with the addition of lithium or the antibiotic demeclocycline ([Ringel and Brick 1986](#)).

CBZ increases plasma high-density lipoprotein (HDL; [O'Neill et al. 1982](#)) and total cholesterol ([Brown et al. 1992](#)) concentrations. However, the HDL-to-total cholesterol ratio does not change ([O'Neill et al. 1982](#)), and thus, CBZ-induced increases in total cholesterol are not likely to be clinically problematic in relation to atherosclerosis ([Brown et al. 1992](#)).

CBZ appears to reduce serum concentrations of both female and male sex hormones ([Verrotti et al. 2011](#)). In common with several other anticonvulsants, CBZ may adversely affect bone density ([Verrotti et al. 2010](#)).

CBZ is teratogenic (former FDA pregnancy category D) and is associated with low birth weight, craniofacial deformities, digital hypoplasia, and, in approximately 3% of births, spina bifida ([Jones et al. 1989](#); [Rosa 1991](#)). Folate supplementation may attenuate the risk of spina bifida, and fetal ultrasound studies may allow early detection. In one study of children born to women with epilepsy, in utero exposure to CBZ or valproate, but not to lamotrigine, had a detrimental effect on child neurodevelopment, although CBZ appeared less likely than valproate to cause major developmental delays ([Cummings et al. 2011](#)).

CBZ is present in breast milk at concentrations about half those in maternal blood, but it may not accumulate in fetal blood ([Froescher et al. 1984](#); [Kuhn et al. 1983](#); [Pynnönen et al. 1977](#); [Shimoyama et al. 2000](#)). Clinicians may prefer to avoid the risk of exposing infants to CBZ in breast milk ([Frey et al. 2002](#)) and may wish to discourage breast feeding in women taking CBZ ([Physicians' Desk Reference 2015](#)).

## Oxcarbazepine

As with CBZ, adverse effects may limit OXC therapy. However, OXC may have tolerability advantages compared with CBZ ([Dam et al. 1989](#)), in part perhaps related to the absence of the CBZ-E metabolite. Of note, OXC lacks black box warnings regarding serious rash, blood dyscrasias, or tissue typing, although OXC still has the class warning regarding increased risk of suicidality. Compared with CBZ, OXC appears to have a lower propensity to cause neurotoxicity and rash. About 75% of patients who develop a rash with CBZ will tolerate OXC. OXC does not appear to require hematological monitoring.

OXC, like CBZ, may cause transaminase elevations and gastrointestinal adverse effects, but there is less weight gain than with valproate ([Rättyä et al. 1999](#)) and less impact on lipids than with CBZ ([Isojärvi et al. 1994](#)). Hyponatremia occurs more commonly with OXC ([Friis et al. 1993](#)) than with CBZ ([Isojärvi et al. 2001a](#)). However, clinically significant hyponatremia is less common than asymptomatic hyponatremia ([Reinstein et al. 2002](#)).

Compared with CBZ, OXC has less impact on female hormone blood concentrations, likely due to its less marked hepatic enzyme induction. However, OXC induction of female hormone metabolism may still decrease the efficacy of hormonal contraceptives ([Fattore et al. 1999](#); [Krämer et al. 1992](#)). OXC, in common with CBZ and several other anticonvulsants, may adversely affect bone density ([Verrotti et al. 2010](#)).

OXC, in contrast to CBZ, has not to date been associated with congenital malformations in humans (former FDA pregnancy category C). Whether this is due to fewer OXC exposures or the absence of the CBZ-E metabolite (rendering OXC less teratogenic) is unknown. OXC is present in breast milk; therefore, as with CBZ, clinicians may prefer to avoid the risk of exposing infants to OXC in breast milk and may wish to discourage breast feeding in women taking OXC ([Physicians' Desk Reference 2015](#)).

## Eslicarbazepine Acetate

Adverse effects may limit OXC therapy, as with CBZ, but owing to structural advantages, tolerability may be better with ESL ([Almeida and Soares-da-Silva 2007](#)). The most commonly reported adverse effects from two epilepsy registration studies included somnolence, dizziness, vertigo, ataxia, abnormal coordination, diplopia, fatigue, and headache ([Physicians' Desk Reference 2015](#)). The risk of rash was low (about 1%). The risk of hyponatremia with ESL is unknown, with rates ranging from 0.6% to 1.3% in premarketing trials ([Zaccara et al. 2015](#)) and rates as high as 3% in postmarketing studies ([Massot et al. 2014](#)). Significant decreases in sodium levels ( $\geq 10$  mEq/L) were more common with ESL than with placebo ([Physicians' Desk Reference 2015](#)). ESL may increase QT interval on electrocardiogram ([Vaz-Da-Silva et al. 2012](#)).

Importantly, ESL, similar to OXC, lacks black box warnings for serious rash, blood dyscrasias, or tissue typing, although ESL still has the (non-black box) class warning regarding increased risk of suicidality.

ESL, like OXC, has not to date been associated with congenital malformations in humans (former FDA pregnancy category C), and ESL is excreted in breast milk ([Physicians' Desk Reference 2015](#)).

---

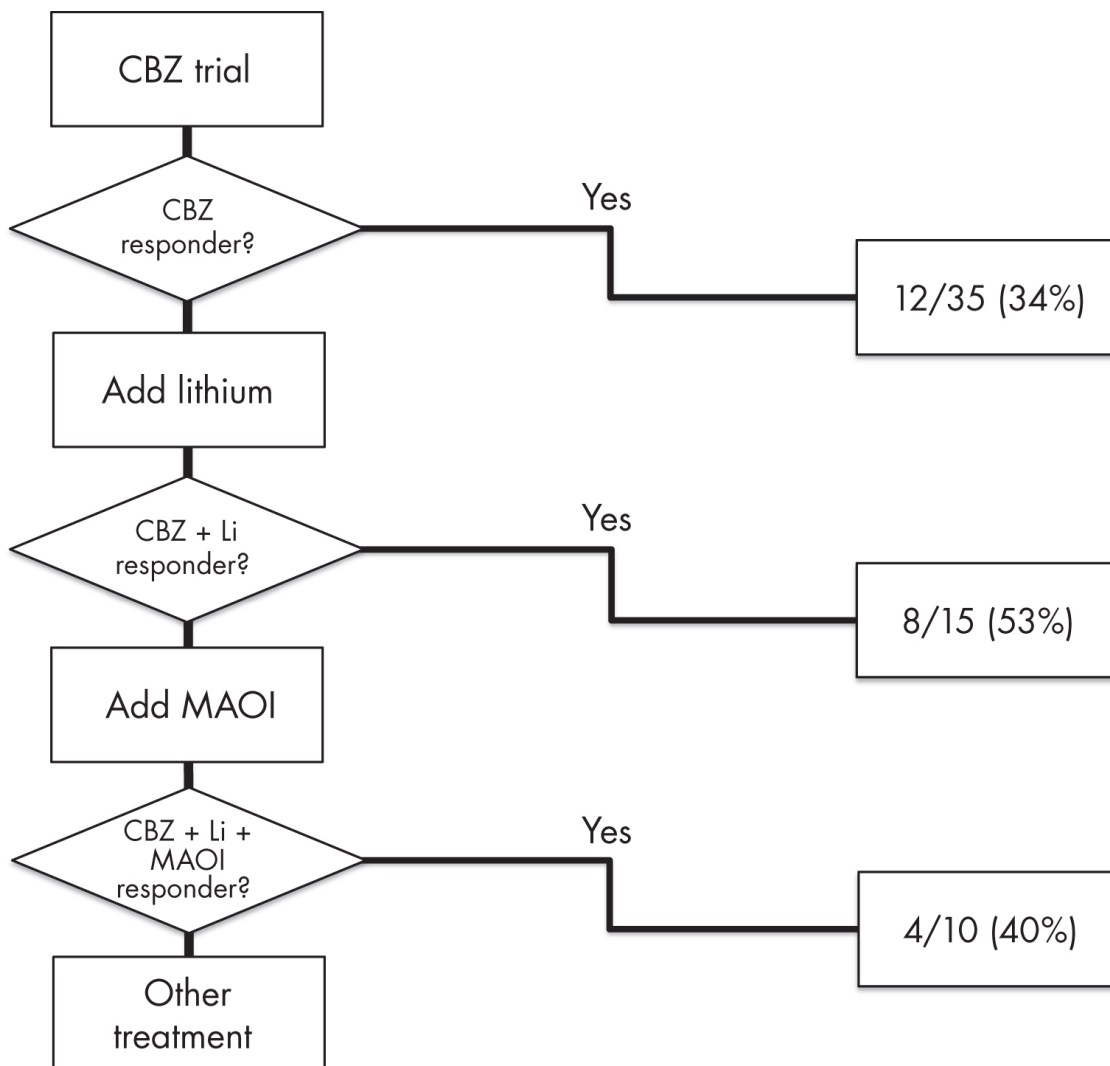

## Drug-Drug Interactions

---

Combination therapy is common in bipolar disorder, with up to two-thirds of patients taking more than one medication concurrently ([Kupfer et al. 2002](#)). Patients with treatment-resistant illness may require a stepped-care approach ([Figure 38-3](#)), and they

appear to be receiving increasingly complex medication regimens ([Frye et al. 2000](#)). CBZ, and to a lesser extent OXC, has clinically significant drug–drug interactions that increase the complexity of managing patients with bipolar disorder.

**FIGURE 38-3.** Stepped-care approach to bipolar depression.

Composite schema of results from three different studies in which patients with bipolar depression received carbamazepine (CBZ) monotherapy ([Post et al. 1986](#)), lithium (Li) added to CBZ ([Kramlinger and Post 1989b](#)), or a monoamine oxidase inhibitor (MAOI) added to CBZ±Li ([Ketter et al. 1995b](#)). Each successive intervention resulted in additional efficacy.

## Carbamazepine

The pharmacokinetic properties of CBZ are typical of older enzyme-inducing anticonvulsants but are atypical among medications prescribed by psychiatrists. CBZ necessitates special care when treating patients concurrently with other medications ([Ketter et al. 1991a, 1991b](#)). Three major principles appear to make important contributions to CBZ drug–drug interactions:

1. **CBZ is a robust inducer of catabolic enzymes (including CYP3A3/4) and decreases the serum concentrations of many medications, including CBZ itself (Table 38-4).** CBZ induces not only CYP3A3/4 and conjugates but also presumably other uncharacterized CYP isoforms. Thus, CBZ decreases the serum concentrations of CBZ itself (autoinduction) (Eichelbaum et al. 1975) and of other medications (heteroinduction). If CBZ is taken concurrently with certain medications, CBZ-induced decreases in serum concentrations can render these medications ineffective (Table 38-4). Moreover, if CBZ is discontinued, serum concentrations of these other medications can increase, potentially leading to adverse effects.

**TABLE 38-4. Selected drugs whose serum concentrations are DECREASED by carbamazepine (and oxcarbazepine)**

<b>Antidepressants</b>	<b>Anticonvulsants</b>	<b>Dihydropyridine CCBs</b>
Bupropion	Carbamazepine	<i>Felodipine</i>
Citalopram	Ethosuximide	Nimodipine
Mirtazapine	Felbamate	
Sertraline	<i>Lamotrigine</i>	<b>Immunosuppressants</b>
Tricyclics	Levetiracetam (?)	Cyclosporine (?)
	Oxcarbazepine	Sirolimus
<b>Antipsychotics</b>	Phenytoin	Tacrolimus
Aripiprazole	Primidone	
Chlorpromazine (?)	Tiagabine	<b>Muscle relaxants</b>
Clozapine	Topiramate	Atracurium
Fluphenazine (?)	Valproate	Cisatracurium
Haloperidol	Zonisamide	Doxacurium
Olanzapine		Mivacurium
Quetiapine (?)	<b>Analgesics</b>	Pancuronium
Risperidone	Alfentanil	Pipercuronium
Thiothixene (?)	<i>Buprenorphine</i>	Rocuronium
Ziprasidone (?)	Fentanyl (?)	Vecuronium
	Levobupivacaine	
<b>Anxiolytics/sedatives</b>	Methadone	<b>Steroids</b>
<i>Alprazolam (?)</i>	Tramadol	Dexamethasone
Buspirone		<i>Hormonal contraceptives</i>
<i>Clonazepam</i>	<b>Anticoagulants</b>	Mifepristone
Eszopiclone (?)	Warfarin	Prednisolone
Midazolam		

*Note. Italic type indicates that serum concentrations of the medication may decrease to a clinically significant extent not only with carbamazepine but also with oxcarbazepine, hindering efficacy of the agent. (?)=unclear clinical significance; CCBs=calcium channel blockers.*

	<b>Anti-infectives</b>	<b>Others</b>
<b>Stimulants</b>	Caspofungin	<i>Paclitaxel</i>
Methylphenidate	Delavirdine	Quinidine
Modafinil	Doxycycline	<i>Repaglinide</i>
	Praziquantel	Theophylline (?)
	Protease inhibitors	Thyroid hormones

*Note.* *Italic type* indicates that serum concentrations of the medication may decrease to a clinically significant extent not only with carbamazepine but also with oxcarbazepine, hindering efficacy of the agent. (?)=unclear clinical significance; CCBs=calcium channel blockers.

- CBZ metabolism (primarily CYP3A3/4) can be inhibited by certain enzyme inhibitors, yielding increases in serum CBZ concentrations and CBZ intoxication** (Table 38-5 and Figure 38-1, top). Autoinduction makes CBZ particularly vulnerable to the effects of enzyme inhibitors. Thus, a variety of agents that inhibit CYP3A3/4 can yield increased serum CBZ concentrations and intoxication (Table 38-5 and Figure 38-1, top).

**TABLE 38-5. Selected drugs that INCREASE serum concentrations of carbamazepine (but not oxcarbazepine)**

<b>Antidepressants</b>	<b>Calcium channel blockers</b>
Fluoxetine	Diltiazem
Fluvoxamine	Verapamil
Nefazodone	
	<b>Hypolipidemics</b>
<b>Anti-infectives</b>	Gemfibrozil
Isoniazid	Nicotinamide
Quinupristin/dalfopristin	
	<b>Others</b>
<b>Azole antifungals</b>	Acetazolamide
Fluconazole	Cimetidine
Itraconazole	Danazol
Ketoconazole	Grapefruit juice
	Omeprazole
<b>Macrolide antibiotics</b>	<i>d</i> -Propoxyphene
Clarithromycin	Ritonavir
Erythromycin	Ticlopidine (?)
Troleandomycin	Valproate (increases CBZ-E)

*Note.* (?)=unclear clinical significance; CBZ-E=carbamazepine-10,11-epoxide.

- CBZ has an active epoxide (CBZ-E) metabolite** (Figure 38-1, top). Valproate inhibits epoxide hydrolase, yielding increased serum CBZ-E (but not CBZ) concentrations (Table

38-5). Free CBZ may also increase because of valproate-induced displacement of CBZ protein binding.

CBZ has a wide variety of pharmacokinetic drug-drug interactions, in excess of and different from those seen with lithium or valproate. In the following subsections, we review CBZ drug interactions with other medications, with agents of particular interest in the management of mood disorders indicated in **boldface** type. The reader interested in detailed reviews of CBZ drug-drug interactions is referred to the review by [Ketter et al. \(1991a, 1991b\)](#).

### Interactions With Mood Stabilizers and Anticonvulsants

The combination of CBZ plus lithium is frequently used in bipolar disorder, and it may provide additive or synergistic antimanic ([Kramlinger and Post 1989a](#)) and antidepressant ([Kramlinger and Post 1989b](#)) effects. The combination is generally well tolerated, with merely additive (as opposed to synergistic or antagonistic) neurotoxicity ([McGinness et al. 1990](#)), which can be minimized by gradual dosage escalation. Pharmacokinetic interactions between these drugs do not occur because lithium has no hepatic metabolism. Adverse effects of lithium and CBZ can be either additive or complementary, so combination therapy decreases the serum concentrations of thyroid hormones in an additive fashion ([Kramlinger and Post 1990](#)), whereas lithium-induced increases in leukocytes and neutrophils override the common benign decreases in these indices seen with CBZ ([Kramlinger and Post 1990](#)). It is important to note that lithium cannot alter the course of the rare severe bone marrow suppression caused by CBZ ([Joffe and Post 1989](#)). Also, the diuretic effect of lithium overrides the antidiuretic effect of CBZ ([Klein 1987](#)). Thus, CBZ will not reverse lithium-induced diabetes insipidus, although lithium can attenuate CBZ-induced hyponatremia ([Klein 1987](#); [Vieweg et al. 1987](#)).

Reports suggest that the combination of CBZ plus **valproate** only is not tolerated but also shows psychotropic synergy ([Keck et al. 1992](#); [Ketter et al. 1992](#); [Tohen et al. 1994](#)). Effective combination treatment with these two medications requires a thorough knowledge of their drug interactions, which can be simplified with the general principle that usual dosages of CBZ should be reduced. Valproate inhibits CBZ metabolism ([Macphée et al. 1988](#)) and also displaces CBZ from plasma proteins, increasing the free CBZ fraction that is active and available to be metabolized ([Macphée et al. 1988](#); [Moreland et al. 1984](#)). Depending on which effect predominates, total serum CBZ concentrations can vary ([Brodie et al. 1983](#); [Kutt et al. 1985](#); [Macphée et al. 1988](#); [Moreland et al. 1984](#); [Rambeck et al. 1987](#)). Valproate inhibits epoxide hydrolase, increasing the serum CBZ-E concentration, at times without altering the total serum CBZ concentration ([Brodie et al. 1983](#); [Rambeck et al. 1987](#)).

These interactions can potentially confuse clinicians, because patients can experience neurotoxicity from elevated serum CBZ-E or free CBZ concentrations even if their serum total CBZ concentrations are at therapeutic levels ([Kutt et al. 1985](#)). CBZ decreases serum valproate concentrations ([Kondo et al. 1990](#)), and its discontinuation can result in increased serum valproate concentrations and toxicity ([Jann et al. 1988](#)). CBZ enzyme induction also increases the formation of the active valproic acid metabolite, 2-propyl-4-pentenoic acid (4-ene-valproic acid; [Kondo et al. 1990](#)), which may be hepatotoxic and may add to teratogenicity ([Nau and Löscher 1986](#); [Scheffner et al. 1988](#)). The risk of fatal hepatitis is of great concern in infants treated with combinations of valproate with other anticonvulsants ([Scheffner et al. 1988](#)), but this risk is much lower in adults ([Dreifuss et al. 1989](#)). As a general rule, clinicians should clinically monitor patients receiving the CBZ-

plus-valproate combination for adverse effects and should consider decreasing the CBZ dosage in advance of adding valproate, and possibly increasing the valproate dosage.

CBZ increases **lamotrigine** metabolism and approximately halves blood lamotrigine concentrations. Thus, lamotrigine dosages can be doubled with this combination. CBZ combined with lamotrigine may have additive neurotoxic effects, probably due to a pharmacodynamic interaction. CBZ even appears to affect **OXC** metabolism; in epilepsy patients, CBZ yielded decreased serum MHD concentrations (McKee et al. 1994).

CBZ induces the metabolism of **CBZ** (autoinduction) and **OXC** (McKee et al. 1994), as well as the metabolism of several older (e.g., ethosuximide, phenytoin, primidone) and newer (e.g., felbamate, **topiramate**) anticonvulsants (Sachdeo et al. 1996), tiagabine (Samara et al. 1998), and **zonisamide** (Ojemann et al. 1986), but not gabapentin (Radulovic et al. 1994) or pregabalin (Brodie et al. 2005). The enzyme-inducing anticonvulsants phenytoin, phenobarbital, primidone, methsuximide, and felbamate decrease serum CBZ levels.

## Interactions With Antidepressants

Antidepressants are commonly combined with mood stabilizers in the treatment of bipolar disorder. These drug-drug interactions may be bidirectional.

**Fluoxetine** (Grimsley et al. 1991; Pearson 1990), **fluvoxamine** (Fritze et al. 1991), and **nefazodone** (Ashton and Wolin 1996; Laroudie et al. 2000; Roth and Bertsch 2001) have been reported to inhibit CBZ metabolism, causing increased CBZ concentrations and toxicity. In addition, parkinsonian symptoms have been reported after adding fluoxetine to CBZ (Gernaat et al. 1991). In contrast, sertraline (Rapeport et al. 1996), paroxetine (Andersen et al. 1991), citalopram (Møller et al. 2001), and mirtazapine (Sitsen et al. 2001) do not appear to alter CBZ metabolism. CBZ appears to decrease serum concentrations of racemic **citalopram** and **escitalopram** (Steinacher et al. 2002). CBZ also appears to induce the metabolism of **mirtazapine** (Sitsen et al. 2001), **mianserin** (Eap et al. 1999), and **sertraline** (Khan et al. 2000; Pihlgård and Eliasson 2002), and (to some extent) that of trazodone (Otani et al. 1996), as well as (most likely) that of vilazodone (Physicians' Desk Reference 2015). Coadministration of CBZ with mirtazapine is of potential concern because mirtazapine has been associated with rare agranulocytosis.

Patients receiving CBZ and **bupropion** have extremely low serum bupropion concentrations and high hydroxybupropion (metabolite) concentrations (Ketter et al. 1995a). Because hydroxybupropion is active, this dramatic decrease in the ratio of bupropion to hydroxybupropion is unlikely to be clinically problematic, and the combination of CBZ and bupropion may often be effective and well tolerated.

CBZ may increase rather than decrease serum levels of transdermal selegiline and its metabolites (Physicians' Desk Reference 2015). Theoretical grounds have been stated for concern about combining CBZ with monoamine oxidase inhibitors (MAOIs; Thweatt 1986), but case reports (Joffe et al. 1985; Yatham et al. 1990) and series (Ketter et al. 1995b) suggest that the addition of phenelzine or tranylcypromine to CBZ may be well tolerated. However, the anti-tuberculosis drug isoniazid, which is also an MAOI, increases CBZ levels.

CBZ appears to induce the metabolism of **tricyclic antidepressants** (TCAs), including amitriptyline (Leinonen et al. 1991), nortriptyline ( ), imipramine (C.S. Brown et al. 1990), desipramine (Baldessarini et al. 1988), doxepin (Leinonen et al. 1991), and clomipramine (De la Fuente and Mendlewicz 1992). Therefore, if patients do not respond to standard dosages of TCAs, TCA and metabolite concentrations should be checked.

## Interactions With Antipsychotics

Combinations of antipsychotics with mood stabilizers are commonly required in severe mania ([American Psychiatric Association 2002](#)) and are increasingly used in bipolar maintenance treatment ([Ketter 2015](#); [Physicians' Desk Reference 2015](#)).

CBZ increases **haloperidol** metabolism ([Ereshefsky et al. 1986](#); [Jann et al. 1989](#); [Kahn et al. 1990](#)), dramatically lowering its blood concentrations, but clinical responses with this combination are varied ([Jann et al. 1989](#); [Kahn et al. 1990](#)). Weaker evidence suggests that CBZ may increase the metabolism of other first-generation antipsychotic agents, including fluphenazine ([Ereshefsky et al. 1986](#); [Jann et al. 1989](#)), chlorpromazine ([Raitasuo et al. 1994](#)), and thiothixene ([Ereshefsky et al. 1986](#)), but not thioridazine ([Tiihonen et al. 1995](#)), and that loxapine, chlorpromazine, and amoxapine may increase CBZ-E concentrations ([Pitterle and Collins 1988](#)). In view of these interactions, serum antipsychotic medication concentrations should be checked if patients fail to respond to standard dosages of antipsychotic agents during combined therapy with CBZ.

Coadministration of **clozapine** with CBZ is not recommended in view of the potential for synergistic bone marrow suppression ([Physicians' Desk Reference 2015](#)). European centers that have used this drug combination report that CBZ decreases clozapine concentrations ([Raitasuo et al. 1993](#)). Thus, clinicians considering the adjunctive use of a psychotropic anticonvulsant with clozapine should use valproate or another anticonvulsant rather than CBZ, except under unusual circumstances.

CBZ increases the metabolism of **olanzapine** ([Linnet and Olesen 2002](#); [Lucas et al. 1998](#)), **risperidone** ([Ono et al. 2002](#); [Spina et al. 2000](#); [Yatham et al. 2003](#)), **quetiapine** ([Grimm et al. 2006](#)), **aripiprazole** ([Physicians' Desk Reference 2015](#)), **ziprasidone** ([Miceli et al. 2000](#)), and possibly lurasidone. CBZ-related decreases in antipsychotic serum levels may interfere with the efficacy of risperidone ([Yatham et al. 2003](#)) and olanzapine ([Tohen et al. 2008](#)) for acute mania.

## Interactions With Anxiolytics and Sedatives

CBZ is commonly coadministered with **benzodiazepines**, with merely additive CNS adverse effects (e.g., sedation, ataxia). CBZ may decrease serum levels of clonazepam ([Lai et al. 1978](#); [Yukawa et al. 2001](#)), alprazolam ([Arana et al. 1988](#); [Furukori et al. 1998](#)), clobazam ([Levy et al. 1983](#)), and midazolam ([Backman et al. 1996](#)), potentially decreasing the efficacy of these agents. The newer hypnotics eszopiclone and zolpidem, which are susceptible to drug interactions involving induction of CYP3A4, may have drug interactions with carbamazepine ([Drover 2004](#)). On the other hand, clonazepam ([Lander et al. 1975](#); [Lehtovaara et al. 1978](#)) and clobazam ([Goggins and Callaghan 1985](#); [Muñoz et al. 1990](#)) appear to have variable effects on CBZ metabolism. Of interest, CBZ may be effective in ameliorating benzodiazepine withdrawal symptoms ([Ries et al. 1989](#)).

## Interactions With Stimulants

Armodafinil and CBZ combination treatment may decrease armodafinil levels by 37% and CBZ levels by 25% ([Darwish et al. 2015](#)). Methylphenidate is metabolized by nonmicrosomal hydrolytic esterases, without involvement of CYP isoenzymes; thus, interactions with CBZ are not expected. However, case reports have suggested that CBZ may decrease methylphenidate serum concentrations in some patients ([Behar et al. 1998](#)).

## Interactions With Calcium Channel Blockers

Of clear clinical importance, elevated serum CBZ concentrations and neurotoxic effects have been reported during concurrent treatment with the nondihydropyridines **verapamil** and **diltiazem** but not with the dihydropyridines nifedipine ([Brodie and](#)

MacPhee 1986; Price and DiMarzio 1988) and nimodipine. These observations are consistent with the finding that verapamil and diltiazem but not nifedipine inhibit the hepatic oxidative metabolism of various drugs (Hunt et al. 1989). Enzyme-inducing anticonvulsants such as CBZ appear to decrease serum concentrations of **dihydropyridines** such as nimodipine (Tartara et al. 1991) and felodipine (Capewell et al. 1988; Zaccara et al. 1993).

### Interactions With Substances of Abuse

Ethanol and CBZ do not interact pharmacokinetically (Dar et al. 1989; Pynnönen et al. 1978). However, CBZ attenuates alcohol withdrawal symptoms (Malcolm et al. 1989). Disulfiram combined with CBZ is well tolerated and does not cause clinically significant changes in serum CBZ and CBZ-E concentrations (Krag et al. 1981). Cigarette smoking does not alter CBZ metabolism (Bachmann et al. 1990), and CBZ does not alter caffeine pharmacokinetics (Wietholtz et al. 1989).

### Interactions With Nonpsychotropic Drugs

CBZ induces the metabolism of diverse medications, raising the possibility of undermining the efficacy of **steroids** (contraceptives, dexamethasone, mifepristone), **methylxanthines** (theophylline, aminophylline), antibiotics (**doxycycline**), **protease inhibitors**, **neuromuscular blockers** (pancuronium, vecuronium, doxacurium), analgesics such as **methadone**, **immunosuppressants** such as sirolimus and tacrolimus, the anticoagulant **warfarin**, and possibly dicumarol (see Table 38-4). In women taking CBZ, dosages of oral contraceptive preparations may need to be adjusted to ensure continued efficacy (Crawford 2002).

Similarly, a variety of medications can increase serum CBZ concentrations and cause clinical toxicity; such medications include **isoniazid**, **azole antifungals** such as ketoconazole, **macrolide antibiotics** such as erythromycin and clarithromycin, **protease inhibitors** such as ritonavir and nelfinavir, **hypolipidemics** such as gemfibrozil and nicotinamide, and the carbonic anhydrase inhibitor **acetazolamide** (see Table 38-5). In addition, other medications such as cisplatin and doxorubicin may decrease serum CBZ levels, potentially leading to inefficacy.

## Oxcarbazepine

In comparison with CBZ, OXC has fewer clinically significant drug-drug interactions. Differences in three major areas appear to contribute importantly to differences between OXC and CBZ with regard to drug-drug interactions:

1. **OXC is only a modest to moderate enzyme (CYP3A4) inducer, which yields clinically significant decreases in serum concentrations of some medications** (see Table 38-4). OXC yields minor enzyme heteroinduction (but not autoinduction), which is clearly less robust than that seen with CBZ, but the effect may be clinically significant for some medications (in *italics* in Table 38-4). In some instances, OXC induction is substantially less robust than CBZ induction, so switching from OXC to CBZ (or vice versa) will make adjustments of doses of other medications necessary.
2. **OXC metabolism (which is primarily by arylketone reductase) is not generally susceptible to enzyme inhibitors.** The absence of autoinduction and the robust actions of cytosol reductases that mediate conversion to the MHD appear to render OXC metabolism not susceptible to the common phenomenon of inhibition by other agents

seen with CBZ. Thus, the medications listed in [Table 38-5](#) that can elevate serum CBZ concentrations and cause neurotoxicity do *not* appear to have such interactions with OXC.

3. **OXC has an active (MHD) metabolite** ([Figure 38-1](#), bottom middle). MHD metabolism, unlike CBZ-E catabolism, is not inhibited by valproate, presumably because of the lack of involvement of epoxide hydrolase in MHD's disposition. Thus, coadministration of valproate with OXC does *not* result in toxicity related to increased MHD.

### Interactions With Mood Stabilizers and Anticonvulsants

OXC, in contrast to CBZ, does not induce valproate metabolism and appears to have less robust effects on **lamotrigine** metabolism ([May et al. 1999](#)). OXC may modestly decrease serum concentrations of topiramate ([May et al. 2002](#)) and levetiracetam ([May et al. 2003](#)). OXC can increase serum phenytoin concentrations, presumably by inhibiting the activity of CYP2C19. The anticonvulsants phenytoin, phenobarbital, primidone, and CBZ may induce OXC metabolism, yielding decreased serum MHD concentrations ([McKee et al. 1994](#)).

### Interactions With Antidepressants

OXC, in contrast to CBZ, does not robustly induce citalopram metabolism.

### Interactions With Antipsychotics

OXC, unlike CBZ, does not robustly induce antipsychotic metabolism.

### Interactions With Anxiolytics and Sedatives

OXC may decrease serum concentrations of **benzodiazepines**.

### Interactions With Calcium Channel Blockers

OXC appears to decrease serum concentrations of **dihydropyridine** calcium channel blockers (which are CYP3A4 substrates) to some extent.

### Interactions With Nonpsychotropic Drugs

OXC, compared with CBZ, also appears to have fewer interactions with nonpsychotropic drugs. Thus, neither the CYP3A4 inhibitor erythromycin ([Keränen et al. 1992a](#)) nor the heteroinhibitor cimetidine ([Keränen et al. 1992b](#)) appears to alter OXC pharmacokinetics in healthy volunteers. In a study in healthy volunteers taking steady-state warfarin, OXC did not significantly alter prothrombin time ([Krämer et al. 1992](#)); therefore, OXC does not appear to robustly induce warfarin metabolism.

However, OXC appears to have a clinically significant interaction with **hormonal contraceptives**. In healthy female volunteers, OXC appeared to decrease ethinylestradiol and levonorgestrel derived from hormonal contraceptives by as much as 50% ([Fattore et al. 1999](#); [Krämer et al. 1992](#)), such that use of higher-dosage forms of estrogen-related oral contraceptives may be indicated.

OXC, like CBZ, may decrease serum concentrations of the analgesic buprenorphine, the anticancer agent paclitaxel, and the antidiabetic agent repaglinide. OXC also yields decreases in serum concentrations of the dihydropyridine calcium channel blocker felodipine (which is also a CYP3A4 substrate). In contrast to the case with CBZ, the CYP3A4 inhibitor erythromycin and the antidepressant viloxazine do not yield clinically significant increases in serum OXC concentrations.

# Eslicarbazepine Acetate

ESL, which shares the same active metabolite as OXC, also has fewer clinically significant drug-drug interactions compared with CBZ. ESL is modestly protein bound, without significant related interactions. ESL does not have significant effects on most CYP enzyme pathways, including 1A2, 2A6, 2B6, 2C9, 2D6, 2E1, and 4A9/11 ([Almeida and Soares-da-Silva 2007](#)). Its three main pharmacokinetic effects are weak induction of CYP3A4, weak induction of UDP-glucuronyl transferases, and weak inhibition of CYP2C19 ([Zaccara et al. 2015](#)).

## Interactions With Mood Stabilizers

Similar to OXC and in contrast to CBZ, ESL does not significantly induce valproate metabolism. Moreover, ESL does not have significant interactions with lamotrigine or topiramate metabolism ([Bialer and Soares-da-Silva 2012](#)). ESL may increase phenytoin levels by up to 35%, presumably because of CYP2C19 inhibition ([Bialer and Soares-da-Silva 2012](#)). When used concurrently with CBZ, however, ESL levels may be decreased by up to 33%, presumably because of CBZ-induced glucuronidation, potentially requiring ESL dosage adjustments ([Bialer and Soares-da-Silva 2012](#)).

## Interactions With Nonpsychotropic Drugs

Because of its modest induction of CYP3A4 activity, ESL may induce moderate reductions in estradiol (up to 42%) in a possibly dose-dependent interaction, potentially reducing the effectiveness of oral contraceptives ([Bialer and Soares-da-Silva 2012](#)). Simvastatin levels may be decreased by up to 40% with ESL coadministration, presumably as a function of CYP3A4 induction ([Zaccara et al. 2015](#)). Effects on warfarin levels are small and within the range of interindividual variability of warfarin pharmacokinetics; therefore, warfarin dosing should be individually optimized to a stable prothrombin international normalized ratio (INR) ([Bialer and Soares-da-Silva 2012](#)). Digoxin and metformin levels are not affected by ESL.

---

## Conclusion

---

In the past, because of the lack of an FDA indication, complexity of use, and methodological concerns regarding earlier efficacy studies, CBZ was generally considered an alternative rather than a first-line intervention in bipolar disorder. However, the approval of a proprietary CBZ beaded extended-release capsule formulation (Equetro) for the treatment of acute manic and mixed episodes in patients with bipolar disorder and the low propensity of CBZ to cause the weight gain and metabolic problems seen with some other agents may lead clinicians to reassess the role of CBZ in the management of bipolar disorder ([Ketter 2015](#)).

OXC, compared with CBZ, has more limited evidence of efficacy in bipolar disorder, but it has enhanced tolerability and fewer drug-drug interactions. MHD (the active metabolite of OXC) and ESL (the prodrug to the *S*-enantiomer of MHD) likewise have enhanced tolerability and fewer drug-drug interactions, but their efficacy in bipolar disorder remains to be established. Thus, with CBZ (but not OXC), common benign leukopenia needs to be distinguished from rare serious aplastic anemia, and patients and caregivers need to be alert to symptoms of this adverse effect. In addition, CBZ (and to a lesser extent OXC) in combination therapy induces the metabolism of other drugs, potentially

undermining their efficacy if the dosage is not adjusted for this lowering effect. Also, other drugs (e.g., erythromycin, verapamil) can inhibit CBZ (but not OXC) metabolism, causing CBZ toxicity. Instructing patients to alert their other caregivers and their pharmacist that they are receiving CBZ may help avoid drug interactions. Informing patients of several of the common interactions can further assist in the warning process, because other practitioners may inadvertently introduce commonly used drugs such as erythromycin with the attendant risk of CBZ toxicity.

CBZ is an important treatment option for patients with bipolar disorder who experience inadequate response or unacceptable adverse effects with lithium and valproate. Awareness of CBZ and OXC pharmacology and potential drug-drug interactions will enable clinicians to provide the safest and most effective care for their patients with bipolar disorder.

## CHAPTER 39

# Gabapentin and Pregabalin

Mark A. Frye, M.D.

Katherine Marshall Moore, M.D.

Alan F. Schatzberg, M.D.

---

## Gabapentin

---

Early observations of enhanced general well-being in epileptic patients treated with anticonvulsants, as well as various early hypotheses of kindling and sensitization proposed as models of affective illness progression ([Weiss and Post 1998](#)), have promoted controlled investigations of anticonvulsant drugs as potential mood-stabilizing agents.

Gabapentin is U.S. Food and Drug Administration (FDA)-approved for the adjunctive treatment of complex partial epilepsy in pediatric patients ages 3-12 years and in patients older than 12 years (with and without secondary generalization) and for the management of postherpetic

neuralgia in adults. A retrospective review of five placebo-controlled trials of gabapentin in more than 700 patients with refractory partial seizure disorder additionally supported the concept of improvement in general well-being, prompting controlled investigation of the drug in primary psychiatric conditions ([Dimond et al. 1996](#)).

## Structure–Activity Relations

Gabapentin, 2-[1-(aminomethyl)cyclohexyl]acetic acid, is a synthetic analog of  $\gamma$ -aminobutyric acid (GABA) ([Figure 39-1](#)).

---

**FIGURE 39-1.** Chemical structure of gabapentin.

## Pharmacological Profile and Mechanism of Action

The mechanism of gabapentin's anticonvulsant and psychotropic action is not fully understood. Gabapentin was originally developed as a GABA analog. As reviewed by [Taylor et al. \(1998\)](#), GABA is the major inhibitory neurotransmitter in the cerebral cortex. Preclinical studies have suggested that gabapentin increases brain and intracellular GABA by an amino acid active transporter at the blood-brain barrier and multiple enzymatic regulatory mechanisms, respectively. In vitro, gabapentin increases the

activity of glutamic acid decarboxylase, the enzyme that converts glutamate to GABA ([Taylor et al. 1992](#)). Conversely, gabapentin has been shown to inhibit GABA transaminase (GABA-T), the enzyme primarily responsible for GABA catabolism ([Löscher et al. 1991](#)). Glutamate metabolism is also modulated by gabapentin. In vitro, gabapentin inhibits branched-chain amino acid aminotransferase (BCAA-T), which is responsible for glutamate synthesis ([Hutson et al. 1998](#)), and activates glutamate dehydrogenase, which is involved in glutamate catabolism ([Goldlust et al. 1995](#)).

These enzymatic regulatory mechanisms that suggest an increased synthesis and decreased degradation of GABA are clinically relevant. Several, but not all, studies have reported decreased levels of cerebrospinal fluid ([Goddard et al. 1996](#); [Gold et al. 1980](#); [Roy et al. 1991](#)), plasma ([Petty et al. 1990](#)), and magnetic resonance (MR) spectroscopic GABA ([Sanacora et al. 1999](#)) in patients with affective illness in comparison with healthy control subjects. Furthermore, increased MR spectroscopic occipital GABA concentrations have been reported with serotonin reuptake inhibitor treatment in depressed patients ([Sanacora et al. 2002](#)) and gabapentin treatment in patients with complex partial epilepsy ([Petroff et al. 1996](#)).

Gabapentin also has been shown to bind to the  $\alpha_2$  subunit receptor of brain voltage-dependent calcium channels, an effect that may relate to the subsequent inhibition of monoaminergic transmission ([Schlicker et al. 1985](#)). There is no known direct activity at the dopamine, serotonin, benzodiazepine, or histamine receptors. However, gabapentin has been reported to increase whole-blood levels of serotonin in healthy control subjects ([Rao et al. 1988](#)).

# Pharmacokinetics and Disposition

All bioavailability, distribution, and elimination parameters are based on the gabapentin molecule itself, as there is no active metabolite. Gabapentin exhibits nonlinear bioavailability most likely related to an active saturable l-amino acid transport carrier present in gut and blood-brain barrier ([McLean 1999](#)). There is no evidence of plasma protein binding, hepatic metabolism, or cytochrome P450 (CYP) autoinduction. Elimination half-life is 6–8 hours, with a recommended three-times-a-day dosing strategy. Gabapentin is eliminated from systemic circulation unchanged by renal excretion. Patients with compromised renal function will show evidence of reduced gabapentin clearance.

## Indications and Efficacy

### **Epilepsy**

Gabapentin currently is FDA approved for use in the adjunctive treatment of partial seizures with and without secondary generalization in adults with epilepsy ([Medical Economics Company 2006](#)). Approval for this indication was based on controlled evaluations of gabapentin at daily dosages of 600–1,800 mg. Additional research has reported efficacy and tolerability for gabapentin monotherapy at daily dosages up to 4,800 mg in patients with refractory epilepsy ([Beydoun et al. 1998](#)). There is no established therapeutic plasma level for seizure control. Gabapentin has a highly favorable side-effect profile, with only mild side effects (sedation, dizziness, and ataxia) commonly reported.

## Nonepilepsy Neurological Conditions

**Neuropathic pain.** Gabapentin received FDA approval for use in the management of postherpetic neuralgia in adults on the basis of two placebo-controlled studies ([Rice et al. 2001](#); [Rowbotham et al. 1998](#)). Gabapentin also has been systemically evaluated in diabetic neuropathy ([Backonja et al. 1998](#)).

The initial postherpetic neuralgia ([Rowbotham et al. 1998](#)) and diabetic neuropathy ([Backonja et al. 1998](#)) studies were randomized, double-blind, placebo-controlled, parallel-group multicenter investigations with three phases of evaluation. The first phase identified the subject population (patients with diabetic neuropathy of 1–5 years' duration [[Backonja et al. 1998](#)] or postherpetic neuralgia of 3 months' duration [[Rowbotham et al. 1998](#)]). The 8-week double-blind phases consisted of a 4-week step titration (week 1, 900 mg; week 2, 1,800 mg; week 3, 2,400 mg; and week 4, 3,600 mg) and a 4-week fixed-dosage period wherein the dosage that was effective and tolerable from the titration phase was held constant. There were no differences in demographics or rates of dropout due to inefficacy or adverse events between the gabapentin group and the placebo group.

Among the 229 postherpetic neuralgia patients ([Rowbotham et al. 1998](#)), greater pain reduction occurred with gabapentin, noted as early as week 2 and maintained throughout the entire study period. Similarly, secondary measures of mood, such as depression, anger-hostility, fatigue-inertia, and physical functioning, were more effectively treated with gabapentin than with placebo. Eighty-three percent of the patients receiving gabapentin

were maintained on the 2,400-mg daily dosage, and 65% were maintained on the 3,600-mg daily dosage.

Among the 165 diabetic neuropathy patients ([Backonja et al. 1998](#)), greater pain reduction (as measured with an 11-point Likert scale) occurred with gabapentin than with placebo; this difference was statistically significant as early as week 2 of the blind titration phase and remained significant for the duration of the 8-week study. Significant reductions in sleep interference related to pain were also reported, as well as improved quality of life. Gabapentin appeared to be well tolerated, with 67% of the patient group being maintained at a maximum daily dosage of 3,600 mg.

Finally, a 7-week placebo-controlled study evaluated gabapentin (1,800 or 2,400 mg/day in three divided doses) in 334 patients with postherpetic neuralgia ([Rice et al. 2001](#)). Pain was significantly reduced with both gabapentin dosages, with similar improvements in sleep. The improvement in pain score was noted as early as week 1 and was maintained throughout the study.

These findings contrast with findings of additional studies that have investigated gabapentin's utility in the management of perioperative pain ([Zhang et al. 2015](#)). In a reanalysis of two randomized controlled trials of adjunctive gabapentin versus adjunctive placebo in patients undergoing total knee ( $n=102$ ) or total hip arthroplasty ( $n=101$ ), gabapentin did not significantly reduce the primary outcome measure of morphine consumption immediately postprocedure, and 24, 48, and 72 hours postsurgery.

**Movement disorders.** Controlled investigations of gabapentin have been conducted in several movement

disorders. These studies were much smaller than the neuropathic pain studies mentioned in the prior section but included amyotrophic lateral sclerosis (ALS) ([Miller et al. 1996](#)), essential tremor ([Ondo et al. 2000](#); [Pahwa et al. 1998](#)), and parkinsonism ([Olson et al. 1997](#)).

In a study of 152 patients with ALS, patients were randomly assigned to receive a 2,400-mg daily dosage of gabapentin or placebo for 6 months. Decline in muscle strength, the primary outcome measure, was slower in the gabapentin-treated patients than in the placebo-treated patients ([Miller et al. 1996](#)).

Controlled studies of gabapentin for essential tremor have reported mixed results. The first 2-week controlled study showed no difference between gabapentin 1,800 mg/day and placebo for treatment of essential tremor ([Pahwa et al. 1998](#)). A second 6-week controlled study evaluating two gabapentin dosages—1,800 mg/day and 3,600 mg/day—in patients with essential tremor found significant improvements in self-report scores, observed tremor scores, and activities of daily living scores in patients who were randomly assigned to receive gabapentin compared with patients who received placebo ([Ondo et al. 2000](#)).

In a 1-month double-blind, placebo-controlled evaluation of gabapentin in 19 patients with advanced parkinsonism, gabapentin at a mean total daily dosage of 1,200 mg was superior to placebo in reducing rigidity, bradykinesia, and tremor, as measured by the United Parkinson's Disease Rating Scale ([Olson et al. 1997](#)). The rigidity and bradykinesia improvements were independent of tremor improvement.

**Migraine headache.** The comorbidity of migraine headache and bipolar disorder is highly prevalent and clinically significant ([Mahmood et al. 1999](#)). Anticonvulsants, for their mood-stabilizing effects and migraine prophylactic properties, appear to be ideal in this patient population. [Mathew et al. \(2001\)](#) suggested that gabapentin is an effective agent for migraine prophylaxis. One hundred forty-three patients with migraine (with and without aura) participated in this three-phase controlled evaluation of gabapentin. Phase 1 was a 4-week single-blind placebo period during which baseline migraine headache frequency was established. Phase 2 was a 4-week double-blind, placebo-controlled, flexible-dosage titration period during which patients received gabapentin at dosages of up to 2,400 mg/day. Phase 3 was an 8-week double-blind, placebo-controlled period during which the dosage of gabapentin was held constant. Patients randomly assigned to receive gabapentin at 2,400 mg/day had significant reductions in migraine attacks in comparison with placebo-treated patients. Dropout rates were higher with gabapentin and were primarily related to drowsiness and somnolence.

## **Anxiety Disorders**

Gabapentin produces a dose-dependent anxiolytic response in animal models ([Singh et al. 1996](#)). Open-trial investigations have reported positive results with add-on gabapentin in the treatment of generalized anxiety disorder (GAD) ([Pollack et al. 1998](#)) and panic disorder ([Pollack et al. 1998](#)), as well as in refractory obsessive-compulsive disorder ([Corá-Locatelli et al. 1998](#)). Findings from controlled investigations of gabapentin in social phobia

([Pande et al. 1999](#)) and in panic disorder ([Pande et al. 2000b](#)) suggested that gabapentin has anxiolytic activity.

The first study was a 14-week randomized, double-blind, placebo-controlled two-site study of 69 outpatients with DSM-IV ([American Psychiatric Association 1994](#))-confirmed social phobia ([Pande et al. 1999](#)). All patients were required to have a score of 50 or greater on the Liebowitz Social Anxiety Scale (LSAS) at baseline. Reductions in the LSAS score served as the primary outcome measure. In the intent-to-treat analysis, gabapentin was more effective than placebo in reducing social anxiety symptoms. The dosage range for gabapentin was 900–3,600 mg/day, with 56% of patients responding to and tolerating the maximum daily dosage of 3,600 mg. Dizziness and dry mouth were significantly more common in patients treated with gabapentin.

The second study was an 8-week randomized, placebo-controlled six-site monotherapy study of 103 patients with DSM-IV-confirmed panic disorder with or without agoraphobia ([Pande et al. 2000b](#)). Gabapentin was dosed flexibly between 600 and 3,600 mg/day. The primary outcome measure was a decrease in the Panic and Agoraphobia Scale (PAS) score. There were no differences in dropout rate. In the intent-to-treat analysis, no difference in PAS score reduction was seen between patients randomly assigned to receive gabapentin and those receiving placebo. In a post hoc stratification between high ( $\geq 20$ ) and low ( $< 20$ ) PAS symptom severity, patients with high symptom severity who were randomly assigned to receive gabapentin had a greater baseline-to-endpoint decrease in PAS score than did those who were randomly assigned to receive placebo. Somnolence, headache, dizziness,

infection, asthenia, and ataxia were more common with gabapentin than with placebo.

## **Bipolar Disorder**

Numerous case reports on and open trials of gabapentin as a mood stabilizer, encompassing more than 400 patients with a pooled response rate between 65% and 70%, have been reviewed elsewhere ([Frye et al. 2000](#); [Yatham et al. 2002](#)).

One double-blind, placebo-controlled outpatient study evaluated add-on gabapentin for the treatment of bipolar I disorder with manic, hypomanic, or mixed symptoms ([Pande et al. 2000a](#)). The first phase of the study involved a 2-week single-blind, placebo lead-in wherein dosages of the subject's primary mood stabilizer (lithium or valproate) could be adjusted to maximal clinical benefit and minimum threshold of therapeutic level (i.e., lithium level of 0.5 mmol/L, valproate level of >50 µg/mL). The second phase was a 10-week double-blind trial in which subjects were randomly assigned to receive gabapentin, at flexible dosages between 600 and 3,600 mg/day (three-times-a-day dosing), or placebo. In the intent-to-treat population, 117 subjects were randomized; no differences in demographic profile or dropout rate were found between the two groups. The primary outcome measure—total decreased score on the Young Mania Rating Scale—was significantly different between groups in favor of add-on placebo. In a post hoc analysis, lithium adjustments in the single-blind placebo lead-in phase were made more frequently in the placebo group than in the gabapentin group; most of these adjustments (9 of 12; 75%) consisted of a dosage increase. This fact suggests either a strong placebo response or the effect of maximizing lithium blood levels to achieve a

greater antimanic response. Of the gabapentin-treated patients who had drug levels measured, nearly 20% had plasma gabapentin levels that were undetectable.

The second controlled study was a 6-week double-blind, placebo-controlled crossover comparative trial of gabapentin monotherapy, lamotrigine monotherapy, and placebo in 35 inpatients with refractory mood disorder ([Frye et al. 2000](#); [Obrocea et al. 2002](#)). In the preliminary analysis ([Frye et al. 2000](#)) and final analysis ([Obrocea et al. 2002](#)), gabapentin demonstrated no better treatment response than placebo in a group of patients with highly refractory bipolar (primarily rapid-cycling) disorder.

There appears to be a marked contrast between the pooled results of the uncontrolled observations (generally positive) and the results of the controlled studies (generally negative). Important limitations of the controlled investigations included maximizing lithium response in the single-blind placebo run-in phase, lack of rigorous compliance assessment, and use of a monotherapy study design in a cohort of patients with primarily rapid-cycling, treatment-refractory illness.

## **Substance-Related Disorders**

Mood-stabilizing anticonvulsants such as divalproex sodium and carbamazepine may be useful in the treatment of alcohol abuse in bipolar disorder ([Malcolm et al. 2001](#)). Gabapentin has been shown to reduce excitability and convulsions in animal models of alcohol withdrawal ([Watson et al. 1997](#)). Its lack of hepatic metabolism, CYP enzyme induction, protein binding, and addictive potential makes gabapentin a potentially useful compound in this patient population.

Gabapentin's potential utility in the treatment of alcohol withdrawal was examined after initial positive reports emerged ([Bozikas et al. 2002](#)). One study demonstrated that gabapentin had efficacy comparable to that of phenobarbital in treating alcohol withdrawal ([Mariani et al. 2006](#)), although another controlled trial did not substantiate gabapentin's benefit over placebo ([Bonnet et al. 2003](#)). In a post hoc analysis ([Bonnet et al. 2007](#)), there was a significant increase in the Profile of Mood States (POMS) vigor subscore in the gabapentin group versus the placebo group; this response was particularly robust in patients with comorbid mild depression.

Despite the conflicting findings regarding gabapentin's efficacy in alcohol withdrawal, its therapeutic benefit in the sleep-disturbance component of alcohol withdrawal syndrome is now recognized. In outpatients with DSM-IV alcohol dependence experiencing persistent insomnia, low-dose gabapentin (mean dose=900 mg at bedtime), in comparison with trazodone, was associated with greater improvement in sleep problems, as assessed with the Sleep Problems Questionnaire ([Karam-Hage and Brower 2003](#)). In another study, gabapentin, in comparison with lorazepam, was associated with significant reductions in self-reported sleep disturbances and daytime sleepiness in outpatients being treated for alcohol withdrawal ([Malcolm et al. 2007](#)).

A 4-week randomized, placebo-controlled, double-blind study evaluated gabapentin's utility in the prevention of relapse to alcohol use ([Furieri and Nakamura-Palacios 2007](#)). After detoxification, 60 men with DSM-IV alcohol dependence who had been consuming, on average, 17 drinks per day for the preceding 3 months were randomly assigned to receive gabapentin (300 mg twice daily) or

placebo. The gabapentin group showed significant reductions in number of drinks per day, percentage of heavy drinking days, and craving for alcohol (specifically automaticity of drinking) as well as an increase in percentage of days abstinent. In a more recent study in 150 individuals with DSM-IV alcohol dependence, the addition of gabapentin to naltrexone was reported to significantly improve drinking outcomes in comparison with naltrexone alone or placebo ([Anton et al. 2011](#)). The largest clinical trial to date examined linear dose effects of gabapentin on alcohol-related insomnia, dysphoria, and craving in patients with DSM-IV alcohol dependence ([Mason et al. 2014](#)). In this 12-week randomized, double-blind trial ( $n=150$ ), evidence of a linear dose response (1,800 mg gabapentin > 900 mg gabapentin > placebo) was found for abstinence, absence of heavy drinking (defined as  $\geq 4$  and  $\geq 5$  drinks/day for women and men, respectively), mood (i.e., improvement), sleep (i.e., sleep quality), and craving (i.e., reduction).

Finally, in a proof-of-concept randomized controlled study in 50 treatment-seeking outpatients with DSM-IV cannabis dependence, gabapentin at 1,200 mg/day was significantly more effective than placebo in reducing cannabis use and decreasing withdrawal symptoms ([Mason et al. 2012](#)).

## Side Effects and Toxicology

Gabapentin has a highly favorable side-effect profile that has been remarkably consistent across controlled studies of diverse disease states. Sedation, drowsiness, and dizziness always have been reported, and ataxia, dry mouth,

infection, and asthenia have been reported in at least one placebo-controlled study.

Adverse events caused by gabapentin are uncommon but can have serious psychiatric implications. Gabapentin-induced hypomania and mania have been reported ([Leweke et al. 1999](#); [Short and Cooke 1995](#)). The controlled study in mania did not report data on the percentage of patients experiencing exacerbation of mania secondary to gabapentin treatment ([Pande et al. 2000a](#)). Gabapentin also has been associated with aggression, both in pediatric epilepsy ([Wolf et al. 1995](#)) and in adult mania ([Pinninti and Mahajan 2001](#)).

Gabapentin has a broad therapeutic index and appears to be safe in overdose. The broadness of the therapeutic index is most likely related to its nonlinear bioavailability secondary to a saturable transport carrier ([McLean 1999](#)).

## Drug-Drug Interactions

Given its lack of hepatic metabolism, absence of CYP autoinduction, and minimal plasma protein binding, gabapentin does not affect levels of anticonvulsant drugs; similarly, gabapentin's pharmacokinetic characteristics do not change when the drug is coadministered with hepatically metabolized anticonvulsants ([Medical Economics Company 2006](#)). However, gabapentin's renal excretion does pose a potential risk when the drug is used concomitantly with lithium.

Although the therapeutic index for gabapentin is large, the safety window for lithium is not. In a pharmacokinetic study examining the effect of gabapentin versus placebo on a single 600-mg dose of lithium, there was no difference in

maximal lithium concentration ( $Li\ C_{max}$ ), time to reach  $C_{max}$ , or area under the curve in 13 patients receiving steady-state gabapentin (mean dose= $3,645.15 \pm 931.5$  mg) compared with those receiving steady-state placebo ([Frye et al. 1998](#)). It is important to emphasize that this study was in a patient population with normal renal function; cases of reversible renal impairment associated with gabapentin have been reported ([Grunze et al. 1998](#)).

## Summary for Gabapentin

Results of controlled studies of gabapentin clearly suggest its efficacy in several medical conditions, including complex partial epilepsy, postherpetic neuropathy, diabetic neuropathy, and migraine headache. Data also clearly suggest gabapentin's benefit in several off-label psychiatric uses, such as alcohol-related abstinence, craving, and mood/anxiety. Conclusions regarding gabapentin's efficacy in ALS, essential tremor, parkinsonism, social phobia, or panic disorder are less clear, either because of positive controlled studies with small sample sizes or because of negative studies. Gabapentin's role as a mood stabilizer is not clearly established. Gabapentin has a favorable pharmacokinetic profile, and its lack of hepatic metabolism is a particular advantage in patients with compromised liver function. Its minimal drug-drug interactions, low risk of toxicity, and benign side-effect profile make it a useful addition to the pharmacopoeia.

**FIGURE 39-2.** Chemical structure of pregabalin

## Pregabalin

Pregabalin is an anticonvulsant drug approved by the FDA for the adjunctive treatment of partial-onset seizures in adults. It is also approved for the treatment of neuropathic pain associated with diabetic peripheral neuropathy, postherpetic neuralgia, and fibromyalgia. Like many of the newer anticonvulsant agents, pregabalin has been evaluated in carefully controlled studies for possible utility in neurological and psychiatric conditions other than primary epilepsy.

## Structure–Activity Relations

Pregabalin, (3S)-3-(aminomethyl)-5-methylhexanoic acid, is a synthetic analog of GABA ([Figure 39-2](#)).

## Pharmacological Profile and Mechanism of Action

Pregabalin, like gabapentin, is a structural analog of the inhibitory neurotransmitter GABA. Pregabalin showed greater potency than gabapentin in preclinical models of epilepsy, pain, and anxiety ([Hamandi and Sander 2006](#)). Despite being a GABA structural analog, pregabalin has no clinically significant effect at either the GABA<sub>A</sub> or the GABA<sub>B</sub> receptor and is not converted metabolically into GABA or a GABA agonist ([Kavoussi 2006](#)). Furthermore, pregabalin does not bind to any serotonergic, dopaminergic, or glutamatergic receptors. It does bind to the  $\alpha_2\delta$  subunit of the presynaptic voltage-gated calcium channel, modulating the release of excitatory neurotransmitters ([Dooley et al. 2002](#); [Kavoussi 2006](#)). In contrast to GABA reuptake inhibitory anticonvulsants (e.g., tiagabine) or anticonvulsants that modulate enzymatic activity related to GABA production (e.g., vigabatrin), pregabalin has no direct GABA reuptake-inhibitory effects or GABA transaminase-inhibiting effects.

## Pharmacokinetics and Disposition

Pregabalin exhibits linear pharmacokinetics and is not associated with any significant protein binding or hepatic metabolism. Its oral bioavailability is greater than 90% and independent of dose. Steady-state plasma levels are generally achieved within 24–48 hours. Administration with food has no clinically significant effect on the extent of absorption or on elimination. The elimination half-life of the drug is approximately 6.5 hours ([Montgomery 2006](#)). Highly lipophilic but not bound to plasma proteins, pregabalin readily crosses the blood-brain barrier. It is primarily renally excreted, with no active metabolites.

Dosage adjustment is required in patients with renal impairment.

Pregabalin does not induce or inhibit CYP enzymes, nor do CYP enzyme inhibitors alter its pharmacokinetics as a consequence.

## Indications and Efficacy

### **Epilepsy**

Several placebo-controlled studies have evaluated pregabalin in the treatment of patients with refractory partial epilepsy ([Elger et al. 2005](#); [Hamandi and Sander 2006](#)). Response rates for pregabalin dosed at 600 mg/day were similar to those reported in other trials of antiepileptic drugs in refractory epilepsy. The study by [Elger et al. \(2005\)](#) showed that pregabalin administered in either fixed or flexible dosages was highly effective and generally well tolerated as an add-on therapy for partial seizures with or without secondary generalization.

### **Nonepilepsy Neurological Conditions**

Four placebo-controlled studies have evaluated pregabalin's efficacy in neuropathic pain ([Dworkin et al. 2003](#); [Freyenhagen et al. 2005](#); [Sabatowski et al. 2004](#); [van Seventer et al. 2006](#)). In the first study ([Dworkin et al. 2003](#)), an 8-week parallel-group, double-blind, placebo-controlled, randomized multicenter trial, patients with postherpetic neuralgia were randomly assigned to receive either pregabalin 600 mg/day (300 mg/day if they had reduced creatinine clearance) or placebo. At study endpoint, a significant decrease in mean pain scores was found for patients treated with pregabalin compared with

those receiving placebo, and this improvement was identified as early as day 2 and maintained throughout the 8 weeks of double-blind treatment. In the second study ([Freynhagen et al. 2005](#)), patients with chronic postherpetic neuralgia or diabetic peripheral neuropathy were randomly assigned to receive placebo, flexible-dosage pregabalin titrated upward to a maximum dosage of 600 mg/day, or fixed-dosage pregabalin at 300 mg/day for the first week followed by 600 mg/day for the remaining 11 weeks. Both flexible- and fixed-dosage pregabalin significantly reduced endpoint mean pain scores and were significantly superior to placebo in improving pain-related sleep interference.

In the third study, [van Seventer et al. \(2006\)](#) evaluated pregabalin (150, 300, or 600 mg/day in twice-daily doses) or placebo in 370 patients with postherpetic neuralgia. At endpoint, significant dose-proportional pain relief was evident among patients who received pregabalin versus placebo. Sleep interference in all pregabalin groups was significantly improved at endpoint. Similar results were obtained in the fourth study ([Sabatowski et al. 2004](#)), which reported improvement in sleep and mood disturbance in patients treated with pregabalin. In total, these four studies showed benefit in pain reduction, sleep improvement, and mood associated with pregabalin treatment. The most common side effects were dizziness, peripheral edema, weight gain, and somnolence.

[Freeman et al. \(2008\)](#) conducted a pooled analysis of data from seven published randomized, placebo-controlled trials encompassing 400 patients with diabetic peripheral neuropathy. The primary outcome measure was change from baseline to endpoint in mean pain score from patients' daily pain diaries. With three-times-daily administration, all

pregabalin dosages (150, 300, and 600 mg/day) significantly reduced pain and pain-related sleep interference in comparison with placebo. With twice-daily administration, only the 600-mg/day dosage showed efficacy. Pregabalin's pain-reducing and sleep-improving properties appeared to be positively correlated with dosage, with the greatest effect observed in patients treated with 600 mg/day.

## **Fibromyalgia**

Pregabalin is the first medication to receive an FDA indication for the treatment of fibromyalgia. Fibromyalgia is a common chronic pain disorder characterized by widespread diffuse musculoskeletal pain and tenderness frequently accompanied by significant psychiatric comorbidity, including fatigue, sleep disturbance, and mood and anxiety disorders. Classifications of disease severity for fibromyalgia have been published by the American College of Rheumatology ([Wolfe et al. 1990](#)). The prevalence of fibromyalgia in the U.S. population is estimated at 2%, with rates higher in adult women than in men ([Arnold et al. 2007](#)).

Three placebo-controlled studies—two focused on acute treatment ([Crofford et al. 2005](#); [Mease et al. 2008](#)) and one focused on relapse prevention ([Crofford et al. 2008](#))—have evaluated pregabalin's efficacy in the treatment of patients with fibromyalgia. In the first study, an 8-week double-blind, randomized, placebo-controlled investigation of pregabalin (150, 300, and 450 mg/day) versus placebo, pregabalin at the 450-mg daily dosage significantly reduced the average severity of pain in comparison with placebo ([Crofford et al. 2005](#)). Sleep improvement was noted at both the 300-mg and the 450-mg daily dosages. Dizziness and somnolence

were the most frequent adverse events. [Arnold et al. \(2007\)](#), in recognition of the large overlap of psychiatric comorbidity in fibromyalgia, conducted a post hoc analysis of the [Crofford et al. \(2005\)](#) study to assess symptoms of anxiety and depression and their impact on pregabalin treatment. Of 529 patients who had enrolled in pregabalin treatment for fibromyalgia, significantly more patients endorsed anxiety symptoms (71%) than endorsed depressive symptoms (56%). Improvement in pain symptoms with pregabalin versus placebo did not depend on baseline anxiety or depression; in fact, 75% of the pain reduction was not explained by improvements in mood and/or anxiety.

In the second study, a 13-week double-blind, placebo-controlled multicenter trial, 748 patients with fibromyalgia were randomly assigned to receive either placebo or pregabalin at dosages of 300, 450, or 600 mg/day (twice-daily dosing) ([Mease et al. 2008](#)). The primary outcome measure was symptomatic relief of pain associated with fibromyalgia, as measured by a mean pain score from an 11-point numeric rating scale (0=no pain; 10=worst possible pain) from patients' daily diaries. Patients in all pregabalin groups showed statistically significant improvement in endpoint mean pain scores as well as in sleep.

In the third study, the Fibromyalgia Relapse Evaluation and Efficacy for Durability Of Meaningful Relief (FREEDOM) trial, pregabalin was evaluated in nearly 600 patients with fibromyalgia ([Crofford et al. 2008](#)). This study included an initial 6-week open-label phase followed by 26 weeks of double-blind treatment with pregabalin or blind substitution with placebo. The primary outcome measure was time to loss of therapeutic response, defined as less

than a 30% reduction in pain or worsening of symptoms of fibromyalgia. Time to loss of therapeutic response was significantly greater for the pregabalin group than for the placebo group, with Kaplan-Meier estimates of time to event showing that half of the placebo group had relapsed by day 19, whereas half of the pregabalin group had still not lost response by trial end.

Finally, pregabalin was investigated as an adjunct to antidepressant medication in fibromyalgia patients with comorbid depression ([Arnold et al. 2015](#)). In this randomized, placebo-controlled, double-blind crossover study, patients on stable treatment with selective serotonin reuptake inhibitor (SSRI) or serotonin-norepinephrine reuptake inhibitor (SNRI) antidepressants were randomly assigned to adjunctive pregabalin or placebo for 6 weeks, followed by a 2-week taper/washout phase and a crossover to the opposite adjunctive condition for another 6 weeks. Mean scores on measures of pain, anxiety, depression, and fibromyalgia impact all significantly improved with adjunctive pregabalin compared with placebo.

## Anxiety Disorders

**Generalized anxiety disorder.** Findings from four placebo-controlled studies contributed to the approval of pregabalin in Europe for GAD ([Montgomery et al. 2006](#); [Pande et al. 2003](#); [Pohl et al. 2005](#); [Rickels et al. 2005](#)). In the first study ([Pande et al. 2003](#)), 276 patients with GAD were randomly assigned to receive pregabalin 150 or 600 mg/day, lorazepam 6 mg/day, or placebo. The 6-week trial included a 1-week placebo lead-in, 4 weeks of blind treatment, and a 1-week taper. The primary efficacy outcome measure was the endpoint Hamilton Anxiety Scale

(Ham-A) score. The mean baseline-to-endpoint decrease in Ham-A total score in all three active-treatment groups (pregabalin 150 mg/day, pregabalin 600 mg/day, and lorazepam 6 mg/day) was significantly greater than the decrease in the placebo group. Percentages of subjects who met a secondary outcome measure, a reduction of 50% or greater in Ham-A score, were significantly higher in the pregabalin 600-mg/day group (46%) and the lorazepam group (61%) than in the placebo group (27%). There were no significant differences in response rates by either definition between patients receiving pregabalin 150 mg/day and patients receiving placebo.

In the second study by [Pohl et al. \(2005\)](#), twice-daily versus three-times-daily dosing of pregabalin was evaluated in a 6-week double-blind, placebo-controlled study. In this study, 250 patients with GAD were randomly assigned to receive pregabalin 100 mg twice daily, 200 mg twice daily, 150 mg three times daily, or placebo. Mean improvement in the Ham-A total score was significantly greater with pregabalin at all three dosages than with placebo. Pairwise comparisons of twice-daily versus three-times-daily dosing found no significant differences in outcome. All three pregabalin groups showed significantly greater improvement in comparison with placebo at endpoint.

In the third study by [Rickels et al. \(2005\)](#), 454 patients with GAD were randomly assigned in a 4-week design to receive pregabalin 300 mg/day, 450 mg/day, or 600 mg/day; alprazolam 1.5 mg/day; or placebo. The primary outcome measure was change from baseline to endpoint in the total Ham-A score. In comparison with the placebo group, all treatment groups showed significantly greater reductions in mean Ham-A total score at last-observation-carried-forward (LOCF) analysis. A significantly higher proportion

of patients in the pregabalin (all dosages) and alprazolam groups than in the placebo group met the endpoint response criterion of 50% or greater reduction in Ham-A total score. The response rate for the 300-mg/day pregabalin group (61%) was significantly higher than that for the alprazolam group (43%).

In the only pregabalin study with an active antidepressant comparator, [Montgomery et al. \(2006\)](#) randomly assigned 421 patients with GAD to 6 weeks of double-blind treatment with pregabalin (400 or 600 mg/day), venlafaxine (75 mg/day), or placebo. The primary outcome measure was change in the Ham-A total score from baseline to LOCF analysis. Pregabalin (both dosages) and venlafaxine produced significantly greater improvement in the Ham-A total score than did placebo. Patients receiving pregabalin 400 mg/day experienced significant improvement in all primary and secondary outcome measures in comparison with those receiving placebo. Rates of discontinuation associated with adverse events were highest in the venlafaxine group (20.4%), followed by the pregabalin 600 mg/day (13.6%), pregabalin 400 mg/day (6.2%), and placebo (9.9%) groups.

Other trials have followed in the wake of these earlier studies, and a recent meta-analysis of seven trials still points to pregabalin's greater efficacy versus placebo in GAD, although the effect sizes are relatively small (approximately 0.35 for psychic anxiety symptoms) ([Boschen 2011](#)). Pregabalin has also been reported to be an effective adjunctive treatment in patients whose GAD symptoms are nonresponsive to SSRI or SNRI therapy ([Rickels et al. 2012](#)).

**Social anxiety disorder.** In a study by [Pande et al. \(2004\)](#), 135 patients with social anxiety disorder were randomly assigned to 10 weeks of double-blind treatment with either pregabalin (low dosage: 150 mg/day; high dosage: 600 mg/day) or placebo. The primary outcome measure was change from baseline to endpoint in the LSAS total score. Patients randomly assigned to receive pregabalin 600 mg/day showed significant decreases in LSAS total score compared with those receiving placebo. Significant differences between high-dosage pregabalin and placebo were also noted on several secondary measures, including the LSAS subscales Total Fear, Avoidance, Social Fear, and Social Avoidance. Low-dosage pregabalin (150 mg/day) was not significantly better than placebo. Somnolence and dizziness were the most frequently reported adverse events. In a more recent study in 329 patients, pregabalin at 600 mg/day—but not at 300 mg/day or 450 mg/day—separated from placebo ([Feltner et al. 2011](#)), a finding consistent with the dosage recommendation of 600 mg/day for efficacy in this disorder. Finally, a long-term study in 153 patients who had responded to an initial course of pregabalin therapy indicated that 450 mg/day was effective as a maintenance treatment in social anxiety disorder ([Greist et al. 2011](#)).

## **Substance-Related Disorders**

As previously noted, pregabalin has no hepatic metabolism and is excreted essentially unchanged in the urine. This pharmacokinetic profile is ideal for patients with alcohol abuse or dependence who have elevated transaminases but need safe, efficacious treatment for symptoms of alcohol withdrawal. Pregabalin's anticonvulsant, analgesic, and anxiolytic properties and potential utility in alcohol-related

disorders were examined in a preclinical study using a mouse model of alcohol dependence ([Becker et al. 2006](#)). Controlled clinical studies of pregabalin in alcohol-dependent patients are needed.

A study in patients with GAD indicated that pregabalin was efficacious in facilitating discontinuation of long-term benzodiazepine therapy ([Hadley et al. 2012](#)).

## Side Effects and Toxicology

In general, the side effects commonly occurring with pregabalin treatment have been mild and not associated with a severity sufficient to warrant drug discontinuation. The most frequently reported symptoms have been dizziness, sedation, dry mouth, edema, blurred vision, weight gain, and concentration difficulty. In controlled clinical trials with pregabalin, significant weight gain (a gain of 7% or more over baseline) was observed in 9% of patients treated with pregabalin, compared with 2% of patients receiving placebo. Pregabalin treatment does not appear to be associated with significant changes in heart rate, blood pressure, respirations, or electrocardiogram measures. Peripheral edema has occurred in a small percentage of patients, but only in rare circumstances has it been identified as severe.

Available preclinical and clinical data suggest that pregabalin has very low abuse liability and is unlikely to produce significant physical dependence. There have been postmarketing reports of angioedema and hypersensitivity in patients treated with pregabalin ([Pfizer 2006](#)).

# Drug-Drug Interactions

Pregabalin does not induce or inhibit CYP enzymes, nor do CYP enzyme inhibitors alter its pharmacokinetics as a consequence. Therefore, hepatic and CYP drug-drug interactions are not relevant when pregabalin is part of a complex polypharmacotherapy regimen. Because of the drug's renal elimination, dosage adjustment is required for patients with renal impairment. To date, no pharmacokinetic drug-drug interactions have been identified. There is some literature to suggest that there can be an additive cognitive impairment when pregabalin is taken in conjunction with oxycodone and that pregabalin may potentiate the effects of lorazepam and alcohol ([Pfizer 2006](#)).

## Summary for Pregabalin

Controlled studies of pregabalin clearly indicate its efficacy in complex partial epilepsy, postherpetic neuropathy, diabetic neuropathy, fibromyalgia, generalized anxiety disorder, and social anxiety disorder. Like gabapentin, pregabalin has a favorable pharmacokinetic profile, with particular advantages in patients with compromised hepatic function. Its minimal drug-drug interactions, low risk of toxicity, and favorable side-effect profile make it a useful addition to the pharmacopoeia.

---

## Conclusion

---

There is increasing interest in the use of anticonvulsant drugs in mood and anxiety disorders. Both gabapentin and pregabalin have demonstrated efficacy for pain, fibromyalgia, and specific anxiety disorders. Gabapentin also appears to have potential use in cannabis and alcohol use disorders. Gabapentin's and pregabalin's use in bipolar disorder have not been demonstrated in controlled clinical trials.

---

### History and Discovery

---

During the clinical development of lamotrigine as a treatment for intractable seizures, improved mood in lamotrigine-treated patients was anecdotally reported ([Jawad et al. 1989](#); [Smith et al. 1993](#)). In 1993, the addition of lamotrigine to an existing antiepileptic drug regimen was evaluated in a small study of 81 patients with epilepsy ([Smith et al. 1993](#)). Lamotrigine-treated patients reported significantly higher levels of happiness and an improvement in perceived internal locus of control. There was no correlation between perceived happiness and changes in seizure frequency or severity. Thus, the investigators

preliminarily concluded that lamotrigine may have an effect on mood independent of its antiepileptic effect.

---

## Structure-Activity Relations and Pharmacological Profile

---

Lamotrigine (3,5-diamino-6-[2,3-dichlorophenyl]-1,2,4-triazine,  $C_9H_7Cl_2N_5$ ; [Figure 40-1](#)) is an antiepileptic drug of the phenyltriazine class that is chemically unrelated to hepatic enzyme inducers (e.g., carbamazepine) and enzyme inhibitors (e.g., valproic acid). Lamotrigine has not been shown to inhibit the reuptake of norepinephrine, dopamine, or serotonin. Although it exerts inhibitory effects at the serotonin 3 (5-HT<sub>3</sub>) receptor, this activity is weak and unlikely to contribute to its therapeutic profile. Lamotrigine does not have high binding affinity to adrenergic ( $\alpha_1$ ,  $\alpha_2$ ,  $\beta$ ), dopamine (D<sub>1</sub>, D<sub>2</sub>),  $\gamma$ -aminobutyric acid (GABA), histamine (H<sub>1</sub>), kappa opioid ( $\kappa$ ), sigma ( $\sigma_1$ ,  $\sigma_2$ ), or muscarinic (M<sub>1</sub>, M<sub>2</sub>) acetylcholine receptors. Lamotrigine inhibits use-dependent sodium channels, allowing continued normal depolarizations while suppressing paroxysmal burst firing encountered in seizures and hypoxic insult.

---

---

## Pharmacokinetics and Disposition

---

Oral lamotrigine is rapidly absorbed with negligible first-pass metabolism. Peak plasma concentrations are reached in approximately 2–4 hours, and its half-life is approximately 25 hours (GlaxoSmithKline [2011](#)). Lamotrigine is approximately 55% bound to plasma proteins and is unlikely to significantly interact with drugs that are highly protein bound. Metabolism is primarily achieved by competitive glucuronic acid conjugation. At steady-state concentrations, the pharmacokinetics of lamotrigine are linear within a dosage range of 100–700 mg/day (Leach et al. [1995](#)). The clearance of lamotrigine is reduced in the setting of renal insufficiency and hepatic disease.

During pregnancy, clinically significant perturbations in lamotrigine levels can occur. Estradiol, which rises during pregnancy, upregulates the expression of uridine diphosphate-glucuronosyltransferase (UGT) 1A4 (UGT1A4) (Chen et al. [2009](#)), an enzyme that catalyzes 90% of lamotrigine conjugation (Fotopoulou et al. [2009](#)). The rate of lamotrigine clearance increases during each trimester, reaching a peak of 330% of baseline clearance by week 32 gestational age (Pennell et al. [2004](#)). The American Academy of Neurology recommends active monitoring of lamotrigine levels during pregnancy (Harden et al. [2009b](#)). Although lamotrigine levels are not routinely obtained in psychiatry because of a lack of well-defined levels for

clinical response, a woman's preconception level could potentially be used as a guide for prophylactically increasing dosage during pregnancy ([Deligiannidis et al. 2014](#)). If lamotrigine dosing has been increased throughout pregnancy, the dosage should be decreased immediately after delivery by 20%-25% to prevent lamotrigine toxicity, as plasma levels are noted to rapidly return to normal during the first few postpartum weeks ([Clark et al. 2013](#)).

---

## Mechanism of Action

---

The mechanism by which lamotrigine achieves its therapeutic effect in the treatment of bipolar disorder is unknown. The inhibition of voltage-activated sodium channels ([Xie and Hagan 1998](#)) may best characterize lamotrigine's mechanism of action. In addition to sodium channel inhibition, lamotrigine antagonizes N-type calcium channels ([Stefani et al. 1996](#); [von Wegerer et al. 1997](#)). Interestingly, one of the most replicated susceptibility genes for bipolar disorder (*ANK3*) codes for a protein that regulates the assembly of voltage-gated sodium channels ([Schulze et al. 2009](#)). These genetic findings, coupled with the action of lamotrigine on sodium and calcium channels, suggest that channelopathies may be involved in the pathophysiology of bipolar disorder. Antiglutamatergic action is another means by which lamotrigine may affect mood. Presynaptic inhibition of voltage- and use-sensitive sodium channels, calcium channels, and potassium channels ([Grunze et al. 1998](#)) is believed to result in decreased release of the excitatory amino acid glutamate. The reduction of glutamate may occur through suppression of

postsynaptic  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors ([Lee et al. 2008](#)). In addition, lamotrigine may increase brain levels of *N*-acetylaspartate, a mechanism believed to enhance neuronal viability, as deficits in *N*-acetylaspartate contribute to excessive glutamatergic tone and subsequent cell death ([Croarkin et al. 2015](#)).

---

## Indications and Efficacy

---

In 2003, lamotrigine was granted approval by the U.S. Food and Drug Administration (FDA) for use in the maintenance treatment of bipolar I disorder to delay the time to recurrence of new mood episodes. Lamotrigine is also indicated for adjunctive antiepileptic therapy in adults and pediatric patients ( $\geq 2$  years of age) with partial seizures, with generalized seizures secondary to Lennox-Gastaut syndrome, or with primary and generalized tonic-clonic seizures, as well as for antiepileptic monotherapy in patients ( $\geq 16$  years of age) with partial seizures (GlaxoSmithKline [2015](#)).

Although lamotrigine is not FDA-approved for acute bipolar depression, clinical evidence suggests that lamotrigine is effective for this indication. Inadequate data are available to recommend use of lamotrigine in unipolar depression. Other conditions in which lamotrigine has shown promising results in clinical trials include management of rapid-cycling bipolar disorder, borderline personality disorder, schizophrenia, and menstrually entrained mood cyclicity.

# Maintenance Therapy in Bipolar I Disorder

Two large randomized, double-blind, parallel-group, placebo-controlled multicenter studies led to the approval of lamotrigine as a maintenance therapy in bipolar I disorder ([Bowden et al. 2003](#); [Calabrese et al. 2003](#)). Both of these paired studies included a screening phase of up to 2 weeks; an 8- to 16-week open-label phase during which lamotrigine was initiated as an adjunctive agent or as monotherapy and other psychotropic drugs were discontinued; and an 18-month double-blind phase during which patients received lamotrigine, lithium, or placebo as maintenance monotherapy. The primary efficacy variable in both studies was time to intervention for any mood episode.

One of the studies ([Bowden et al. 2003](#)) evaluated subjects who were or had recently been in a manic, hypomanic, or mixed state. The other study ([Calabrese et al. 2003](#)) examined subjects who were or had recently been depressed. Both lamotrigine and lithium were superior to placebo in delaying the time to intervention for any mood episode ( $P=0.018$  for previously manic;  $P=0.029$  for previously depressed). Lamotrigine, but not lithium, was superior to placebo in prolonging the time to a depressive episode ( $P=0.015$  for previously manic;  $P=0.047$  for previously depressed). Lithium, but not lamotrigine, was superior to placebo in prolonging the time to a manic, hypomanic, or mixed episode ( $P=0.006$  for previously manic;  $P=0.026$  for previously depressed). In a post hoc analysis of these two studies, both lithium and lamotrigine were more effective than placebo in prolonging the time to any mood relapse and manic or hypomanic relapse, but only

lamotrigine was superior to placebo in delaying depressive relapse (Goodwin et al. 2004). An open-label study conducted in a clinical setting did not find a significant difference between lithium and lamotrigine in preventing any mood, manic or hypomanic, or depressive relapse (Licht et al. 2010).

In the interpretation of maintenance-phase data, it is important to distinguish between efficacy in relapse prevention and true prophylactic efficacy (Ghaemi et al. 2004). Mood episodes of the same polarity as the index episode that occur during the initial 2 months following recovery are generally regarded as *relapses*, and therefore are considered as being still part of the acute recovery period. Alternatively, mood episodes that occur beyond this time frame, during the period of remission, are regarded as *recurrences*. To test the true maintenance efficacy of lamotrigine, Calabrese et al. (2006) conducted a post hoc analysis of the two double-blind 18-month maintenance trials that compared lamotrigine and lithium against placebo. When all subjects who experienced a relapse to a mood episode of the same polarity as the index episode within 90 days of randomization were excluded, both lamotrigine and lithium were found to be more effective than placebo in delaying the time to intervention for a mood episode ( $P=0.02$  for lamotrigine;  $P=0.01$  for lithium). Similar results were found when patients who relapsed to a mood episode of the same polarity as the index episode within 180 days of randomization were excluded, suggesting that lamotrigine and lithium possess true maintenance efficacy.

# Acute Monotherapy and Adjunctive Therapy of Bipolar Depression

## Monotherapy of Bipolar Depression

A series of double-blind, placebo-controlled multicenter studies of lamotrigine was completed to replicate and extend preliminary open-label prospective findings suggesting moderate to marked efficacy in bipolar depression ([Calabrese et al. 1999a](#)). The first study in this series evaluated the efficacy and safety of two dosages of lamotrigine compared with placebo in the acute treatment of a major depressive episode in 195 patients with bipolar I disorder ([Calabrese et al. 1999b](#)). Outpatients received lamotrigine (50 or 200 mg/day) or placebo as monotherapy for 7 weeks. Assessments using the a priori primary outcome measure, the Hamilton Rating Scale for Depression (Ham-D), as well as several secondary outcome measures—including the Montgomery-Åsberg Depression Rating Scale (MADRS) and the Severity of Illness and Improvement subscales of the Clinical Global Impression Scale (CGI-S and CGI-I, respectively)—were conducted at 4 days and then weekly. Lamotrigine at a dosage of 200 mg/day showed significant antidepressant efficacy on the MADRS, CGI-S, and CGI-I compared with placebo. However, lamotrigine did not separate from placebo on the overall Ham-D score. Despite the promising findings in this first study, four later monotherapy trials with randomized, parallel-group, placebo-controlled designs failed to find differences between lamotrigine and placebo, most likely because of a high placebo response rate (40%–50%) ([Calabrese et al. 2008](#)).

To clarify the effects of lamotrigine in acute bipolar depression, [Geddes et al. \(2009\)](#) conducted a systematic meta-analysis of individual patient data from 1,072 participants in five randomized controlled trials comparing lamotrigine with placebo. The pooled analysis found that a greater proportion of patients receiving lamotrigine than of those receiving placebo showed response on both the Ham-D and the MADRS ( $P=0.002$ ). However, the advantage of lamotrigine over placebo was larger in more severely depressed patients.

Because of the modest effect sizes when lamotrigine is prescribed as monotherapy, the *S3 Guideline for Diagnosis and Treatment of Bipolar Disorders* collaboratively developed by [the German Society for Bipolar Disorder and the German Society of Psychiatry, Psychotherapy and Nervous Diseases \(2012\)](#) stated that whereas lamotrigine may be used for bipolar depression, it is not considered a first-line treatment ([Köhler et al. 2014](#)). The *Guidelines for the Biological Treatment of Bipolar Disorders: Update 2010* from the World Federation of Societies of Biological Psychiatry recommended use of lamotrigine for acute bipolar depression on the basis of the overall positive results of the meta-analysis by [Geddes et al. \(2009\)](#), the drug's effectiveness in severe depression, and the positive clinical experience associated with this agent ([Grunze et al. 2010](#)). The *Collaborative Update of CANMAT Guidelines for the Management of Patients With Bipolar Disorder* of the Canadian Network for Mood and Anxiety Treatments and the International Society for Bipolar Disorders also recommended lamotrigine as a first-line agent for the treatment of acute bipolar depression ([Yatham et al. 2013](#)). Although negative controlled studies outweigh positive studies of lamotrigine administered as monotherapy for

bipolar depression, the negative findings in individual trials may be more a reflection of the patient composition than of a property of the drug itself, given the lack of a comparator arm to determine assay sensitivity and the relatively high rates of placebo response ([Grunze et al. 2010](#)).

In an effort to identify the symptomatic dimensions that may be responsive or unresponsive to lamotrigine, [Mitchell et al. \(2013\)](#) applied factor analysis to a large sample of depressed patients recruited for two separate double-blind, placebo-controlled trials of lamotrigine. Results suggested that lamotrigine's beneficial effect in bipolar depression is largely limited to two core aspects of bipolar depressive symptomatology—namely, depressive cognitions and psychomotor disturbance. Lamotrigine was unlikely to provide benefits for weight gain, insomnia, anergia, or anxiety ([Mitchell et al. 2013](#)).

To date, only three compounds are FDA approved for the treatment of acute bipolar depression: an olanzapine-fluoxetine combination (OFC), quetiapine, and lurasidone. To compare lamotrigine's efficacy in managing bipolar depression with that of an established agent, a head-to-head randomized, double-blind, parallel-group study of lamotrigine and OFC was conducted over 7 weeks in patients with bipolar I disorder in an acute depressive phase ([Brown et al. 2006](#)). The study randomly assigned 410 subjects to either lamotrigine (titrated to 200 mg/day;  $n=205$ ) or OFC (6/25, 6/50, 12/25, or 12/50 mg/day;  $n=205$ ). Overall response and remission rates were comparable between the active agents, although differences did emerge in regard to tolerability profiles. The incidence of adverse events involving suicidal and self-injurious behavior was higher among patients taking lamotrigine (3.4%) than among those taking OFC (0.5%;

$P=0.037$ ). However, significant differences in mean change from baseline to endpoint for clinically relevant laboratory and physiological parameters favored treatment with lamotrigine, including measures such as hemoglobin A1c, prolactin, total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, triglycerides, and body weight. This study was subsequently extended to 25 weeks. At study endpoint, no significant differences were found between OFC and lamotrigine in response, remission, or relapse as measured by change in MADRS total score, although OFC was superior to lamotrigine in reducing depressive and manic symptoms ([Brown et al. 2009](#)).

### **Adjunctive Therapy of Bipolar Depression**

In a trial comparing lamotrigine with placebo in the adjunctive treatment of bipolar I and II depression ([van der Loos et al. 2009](#)), all patients were required to be taking lithium maintained at a therapeutic blood level (0.6–1.2 mmol/L) prior to random assignment to lamotrigine ( $n=64$ ) or placebo ( $n=60$ ) for 8 weeks. Response was assessed at endpoint using the MADRS (primary outcome measure) and the CGI Scale–Bipolar Version (CGI-BP; [Spearing et al. 1997](#)). The change from baseline to endpoint on the MADRS was significantly greater in lamotrigine-treated subjects (15.4) compared with those receiving placebo (11.0;  $P=0.02$ ). A higher percentage of patients responded (as measured by a  $\geq 50\%$  reduction in MADRS score) to adjunctive lamotrigine (51.6%) compared with placebo (31.7%;  $P=0.030$ ), although no difference was observed in the response rate based on the CGI-BP (64.1% for lamotrigine vs. 48.3% for placebo;  $P=0.10$ ). Following the open-label addition of paroxetine for another 8 weeks in

nonresponders, the change in MADRS scores from baseline to week 16 between lithium plus lamotrigine (plus paroxetine in nonresponders) and lithium plus placebo (plus paroxetine in nonresponders) was not significantly different ( $-17.91$  vs.  $-15.40$ ;  $P=0.25$ ) ([van der Loos et al. 2010](#)). After 16 weeks, all responders in both groups were followed for 68 weeks or until a relapse or recurrence of a depressive or manic episode occurred. Time to relapse or recurrence was longer for the lamotrigine group (median time=10.0 months; 95% confidence interval [CI]=1.1-18.8) than for the placebo group (3.5 months; 95% CI=0.7-7.0]) ([van der Loos et al. 2011](#)).

## Additional Uses

### Maintenance Treatment of Rapid-Cycling Bipolar Disorder

[Calabrese et al. \(2000\)](#) conducted a maintenance study with lamotrigine in rapid-cycling bipolar disorder. The difference between the lamotrigine and placebo treatment groups in time to additional pharmacotherapy for a developing or fully developed mood episode did not achieve statistical significance. However, overall survival time in the study (i.e., time to dropout for any reason) was significantly different between the treatment groups in favor of lamotrigine ( $P=0.036$ ). When patients with bipolar I and II subtypes were compared, lamotrigine-treated bipolar II disorder patients had a significantly longer median survival of 17 weeks compared with a median of 7 weeks for placebo-treated patients ( $P=0.015$ ).

## **Menstrual Cycle-Related Mood Variability in Women With Bipolar Disorder**

Because lamotrigine is implicated in the modulation of glutamatergic and potentially GABAergic signaling, it has been hypothesized that lamotrigine may affect menstrual cycle-related alterations in neurotransmitter activity. Among women with bipolar disorder whose regimens included lamotrigine, less intraindividual variability in mood was evidenced across menstrual cycle phases ([Robakis et al. 2015](#)). Although the effect was small, it represents preliminary evidence for lamotrigine's potential utility in treating menstrually entrained mood cyclicity.

## **Acute Treatment of Bipolar Mania or Schizophrenia**

Lamotrigine does not appear to possess acute antimanic activity. In two placebo-controlled trials in patients with bipolar I disorder experiencing an acute manic or mixed episode, including a 3-week monotherapy trial and a 6-week add-on trial ([Bowden et al. 2000](#)), lamotrigine failed to separate from placebo on the primary outcome measure, change in symptom severity on the Mania Rating Scale (MRS). Similarly, in two placebo-controlled trials, lamotrigine used as an adjunct to antipsychotic treatment was not more effective than adjunctive placebo (i.e., antipsychotic monotherapy) as measured by change in mean Positive and Negative Syndrome Scale total scores, although in one trial, a cognitive composite score improved more with lamotrigine than with placebo ([Goff et al. 2007](#)).

## **Monotherapy or Adjunctive Therapy of Major Depressive Disorder**

Limited evidence suggests that lamotrigine may be effective in the treatment of unipolar major depressive disorder, either as monotherapy or as an adjunct to conventional antidepressants. Three double-blind, placebo-controlled multicenter trials of lamotrigine monotherapy for nonrefractory major depressive disorder did not detect a significant drug-placebo difference (GlaxoSmithKline 2008a, 2008b, 2011). Lamotrigine also did not separate from placebo in a small double-blind, fixed-dose study comparing the addition of lamotrigine versus placebo to paroxetine treatment (Normann et al. 2002). In two small prospective studies of lamotrigine augmentation of antidepressant treatment in refractory depression, the open-label trial reported improvement on the CGI-I and MADRS (Gabriel 2006), but the double-blind trial found no significant drug-placebo differences at study endpoint (Santos et al. 2008). A subsequent double-blind, placebo-controlled trial of lamotrigine in treatment-refractory depression by Barbee et al. (2011) also did not detect statistically significant differences between the lamotrigine and the placebo groups, although benefit was observed in study completers and those with more severe illness. A systematic review and meta-analysis examining response and remission rates in studies of lamotrigine augmentation of antidepressants in treatment-refractory unipolar depression concluded that lamotrigine was no more efficacious than placebo (Zhou et al. 2015). Thus, there is little evidence to recommend lamotrigine as a pharmacological option for treatment of major depressive disorder.

## **Borderline Personality Disorder**

Lamotrigine's potential utility in borderline personality disorder was investigated in two randomized, double-blind, placebo-controlled trials (total  $N=55$ ) ranging in duration from 8 to 12 weeks ([Reich et al. 2009](#); [Tritt et al. 2005](#)). Significant improvements in anger, impulsivity, and affective instability were reported.

---

## Dosing Recommendations

---

The recommended dosing schedule for lamotrigine in adults involves initiating therapy with 25 mg daily for the first 14 days and then advancing to 50 mg daily for the third and fourth weeks of treatment. During the fifth week of treatment, lamotrigine can be increased to 100 mg daily, followed by titration to 200 mg daily during the sixth and seventh weeks of treatment. When lamotrigine is used to augment valproate therapy in adult patients, the recommended titration schedule begins with 25 mg every other day for 14 days, advances to 25 mg daily for 14 days, and then increases to 50 mg daily and 100 mg daily beginning at each of the fifth and sixth weeks of treatment, respectively ([Table 40-1](#)). The titration process for lamotrigine used as an adjunct to treatment with an enzyme-inducing antiepileptic drug begins with 50 mg daily for 14 days, advances to 100 mg daily (taken in divided doses) for 14 days, and eventually increases to a target maintenance dosage of 400 mg/day ([Table 40-2](#)). No published data support improved efficacy for lamotrigine in the treatment of bipolar disorder at dosages greater than 200 mg/day in the absence of an enzyme inducer.

Additionally, there is no clear association between serum levels of lamotrigine and measures of affective response.

**TABLE 40-1. Recommended titration schedule for lamotrigine for patients with bipolar disorder taking valproate**

<b>Week</b>	<b>Dosage</b>
Weeks 1 and 2	25 mg every other day
Weeks 3 and 4	25 mg daily
Week 5	50 mg daily
Week 6	100 mg daily
Week 7	100 mg daily

*Note.* The usual maintenance dosage when lamotrigine is added to valproate is 100 mg/day.

*Source.* Adapted from [GlaxoSmithKline 2015](#).

**TABLE 40-2. Recommended titration schedule for lamotrigine when used as monotherapy and when added to an enzyme-inducing antiepileptic drug regimen\* (without valproate)**

	<b>For patients NOT TAKING an enzyme- inducing antiepileptic drug regimen* and not taking valproate</b>	<b>For patients TAKING an enzyme- inducing antiepileptic drug regimen* and not taking valproate</b>

---

Weeks 1 and 2	25 mg/day	50 mg/day
Weeks 3 and 4	50 mg/day	100 mg/day (in two divided doses)
Week 5	100 mg/day	200 mg/day (in two divided doses)
Week 6	200 mg/day	300 mg/day (in two divided doses)
Usual maintenance dosage	200 mg/day	400 mg/day (in two divided doses)

---

\*Carbamazepine, phenytoin, phenobarbital, primidone, and rifampin have been shown to increase the apparent clearance of lamotrigine.

*Source.* Adapted from [GlaxoSmithKline 2015](#).

## Side Effects and Toxicity

---

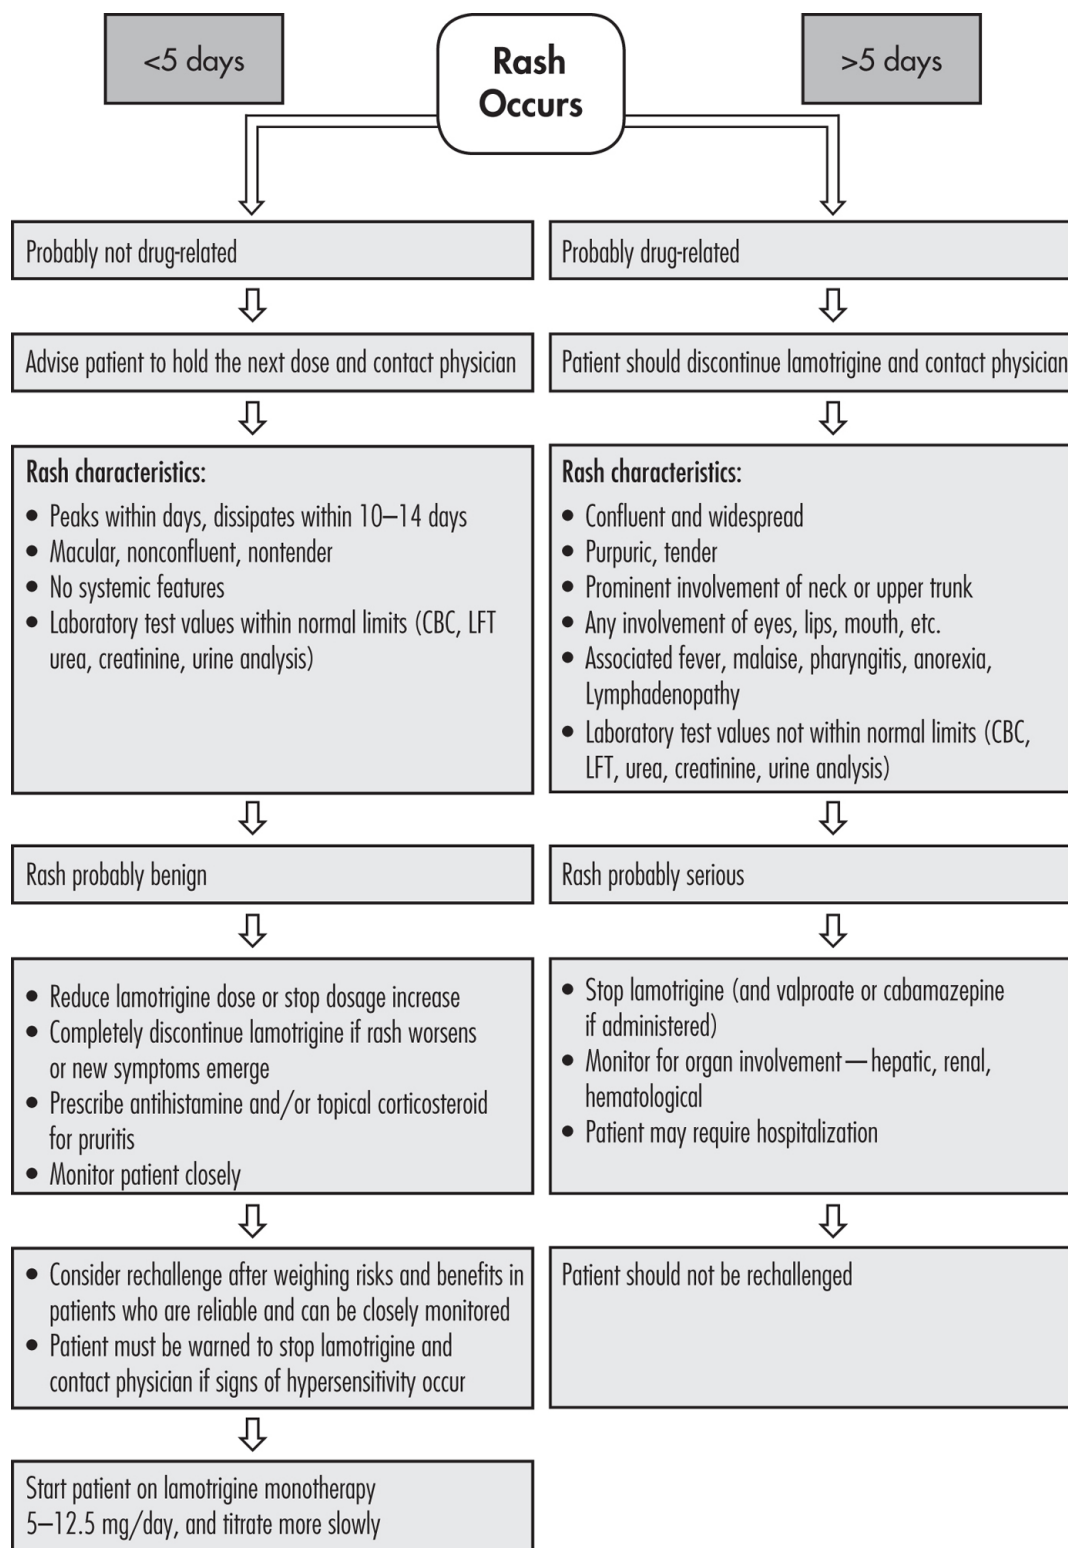

In controlled monotherapy trials of lamotrigine in the treatment of mood disorders, the drug was associated with headache, changes in sleep habits, nausea, and dizziness ([Bowden et al. 2004](#)). In randomized trials of lamotrigine in mood disorders, the prevalence of rash did not exceed that of placebo; however, rash is generally recognized as the side effect most likely to significantly complicate lamotrigine's clinical use.

# Skin Reactions

In early epilepsy trials, rash led to hospitalization and treatment discontinuation or Stevens-Johnson syndrome in 0.3% of the adults taking lamotrigine ([Calabrese et al. 2002](#)). The annual incidence of serious drug-based skin reactions associated with lamotrigine—such as Stevens-Johnson syndrome, DRESS (drug rash with eosinophilia and systemic symptoms), and toxic epidermal necrolysis—was highest in 1993 (4.2%) but steadily declined and had stabilized by 1998 (0.02%). This reduction in incidence was likely attributable to the manufacturer's dosage revision in 1994, which advised a more protracted titration schedule ([Calabrese et al. 2002](#); [Messenheimer et al. 1998](#)). It is well documented that the risk of rash is heightened by exceeding the recommended initial dosage or the rate of dosage escalation of lamotrigine, and by coadministering lamotrigine with valproic acid. The risk is also greater in children younger than 12 years. Nearly all cases of life-threatening rashes caused by lamotrigine have occurred within 2–8 weeks of treatment initiation (GlaxoSmithKline [2015](#)).

The most common lamotrigine-associated rash is an exanthematic maculopapular or morbilliform eruption that is benign. However, a clinically similar eruption may be associated with more rare and serious systemic hypersensitivity reactions ([Guberman et al. 1999](#)). [Figure 40-2](#) presents a decision-making algorithm for the management of benign and serious rashes ([Calabrese et al. 2002](#)). A serious lamotrigine rash is usually confluent with prominent facial and neck involvement. The rash may be tender or have a purpuric or hemorrhagic appearance. It may be accompanied or preceded by fever, malaise,

pharyngitis, anorexia, or lymphadenopathy ([Guberman et al. 1999](#)). Thus, all patients who develop a rash during the first few months of lamotrigine therapy should be instructed to hold the next dose and immediately seek medical consultation. The greatest risk of rash appears to be during the first 8 weeks of treatment. A rash during the first 5 days of therapy is usually due to a nondrug cause. Because immune tolerance to lamotrigine is lost following interruption of dosage for more than 1 week, patients should be instructed to resume lamotrigine at the prior initial start-up dose and to gradually titrate upward whenever therapy has been interrupted for more than a few days.

## Aseptic Meningitis

Rare cases of aseptic meningitis in association with lamotrigine have occurred ([Boot 2009](#); [Kilfoyle et al. 2005](#); [Lam et al. 2010](#)). Clinical manifestations include meningismus, photophobia, headache, vomiting, and fever. Symptoms were reported to appear within 1 day to 1.5 months following initiation of treatment. In several cases, sudden and severe symptoms of meningitis have occurred within minutes of reintroducing lamotrigine. In most cases of drug-induced aseptic meningitis, there is complete recovery once the offending agent has been discontinued ([Moris and Garcia-Monco 1999](#)).

## Weight-Neutral Effects

In comparison with other agents used in the management of bipolar disorder, a distinctive feature of lamotrigine is its weight-neutral tolerability profile ([Sachs et al. 2006](#)). A post hoc analysis found that nonobese patients taking lamotrigine are unlikely to experience a change in weight. However, obese patients are significantly more likely to lose weight with lamotrigine and to gain weight with lithium ([Bowden et al. 2006](#)).

# Safety in Overdose

Among 493 cases of lamotrigine toxicity in overdose, the majority of patients (52.1%) experienced no toxic clinical effects ([Lofton and Klein-Schwartz 2004](#)). Common symptoms included drowsiness, vomiting, nausea, ataxia, dizziness, and tachycardia. Rare cases of coma, seizures, heart conduction delay, and respiratory depression have been reported in overdose. Some ingestions of lamotrigine involving quantities up to 15 grams have been fatal.

# Use During Pregnancy and Lactation

For women who are capable of becoming pregnant or who are already pregnant, lamotrigine may represent a safer option than valproate because of its favorable tolerability profile and lower risk of major congenital malformations ([Campbell et al. 2014](#)). An observational study by [Newport et al. \(2008\)](#) examined risk of illness recurrence in pregnant women with stable bipolar disorder who continued lamotrigine treatment during pregnancy ( $n=10$ ) compared with those who discontinued mood stabilizer therapy during pregnancy ( $n=16$ ). The risk of illness recurrence was 3.3 times lower when lamotrigine was continued (30.0% recurrence [3/10] vs. 100% recurrence [16/16] when patients discontinued mood stabilizers;  $P<0.0001$ ), suggesting that lamotrigine may provide protective effects in pregnancy.

Potential adverse effects on the developing fetus of mothers receiving lamotrigine have been suggested by data collected as part of international pregnancy registries ([Cunnington et al. 2005](#); [Holmes et al. 2008](#)). As with any

mood stabilizer, lamotrigine use during pregnancy represents an inherent dilemma for clinicians and expectant mothers, who must balance the risks associated with untreated bipolar disorder in the mother against the risk of major congenital malformations in the fetus. Neural tube defects are estimated to occur in 1%–5% of neonates exposed to valproate or carbamazepine in the first trimester. The risk of neural tube defects with lamotrigine appears lower than that with valproate. However, studies have yielded mixed findings regarding an increased risk for teratogenesis with lamotrigine. In the North American Antiepileptic Drug Pregnancy Registry, the risk of cleft palate, cleft lip, or both for infants exposed to lamotrigine was 7.3 out of 1,000, approximately 10 times higher than the risk for unexposed infants ([Holmes et al. 2008](#)). An analysis from an Australian pregnancy registry found no statistically significant difference between the risk of fetal malformations among women exposed to lamotrigine monotherapy during pregnancy and the risk among pregnant women with epilepsy taking no antiepileptic drugs ([Vajda et al. 2010](#)).

Although early reports suggested a likely relation between higher dosages of lamotrigine (>400 mg/day) taken by a woman during pregnancy and greater risk of a major congenital malformation in her offspring, a more recent report found minimal differences in risk between high- and low-dosage lamotrigine exposures ([Campbell et al. 2014](#)). Nevertheless, limiting the dosage during the first trimester should be considered ([Harden et al. 2009a](#)). Lamotrigine is listed as Pregnancy Category C in terms of teratogenic effects.

A prospective observational study that followed children born to mothers who took antiepileptic medications as

monotherapy during pregnancy found at the 3-year assessment that children exposed to lamotrigine in utero had higher IQ scores compared with children exposed to valproate, carbamazepine, or phenytoin ([Meador et al. 2009](#)).

In newborns of mothers receiving lamotrigine, extensive placental transfer of drug has been found to occur, with umbilical cord concentrations approaching those of maternal serum ([Ohman et al. 2000](#)). Plasma lamotrigine concentrations in nursing infants are approximately 23%–50% of maternal levels.

---

## Drug-Drug Interactions

---

Lamotrigine is not known to inhibit the activity of the cytochrome P450 2D6 enzyme. However, the addition of adjunctive lamotrigine to enzyme inducers such as carbamazepine, phenytoin, primidone, and phenobarbital decreases lamotrigine plasma concentrations by approximately 40%–50% ([Hahn et al. 2004](#)). The inducing effect of oxcarbazepine is approximately half that of carbamazepine ([Weintraub et al. 2005](#)). Because lamotrigine is nearly exclusively metabolized by glucuronidation, the introduction of adjunctive valproate (an enzyme inhibitor) results in immediate and successful competition for metabolism, with resultant increases in half-life.

Evidence has emerged that oral contraceptives containing estrogen have the potential to decrease serum concentrations of lamotrigine by up to 64% ([Sabers et al. 2001, 2003](#)). Progestins, however, are not associated with a

decrease in lamotrigine levels ([Reimers et al. 2005](#)). During the long-term treatment of bipolar disorder, use of ethinyl estradiol-containing compounds may require an increase in the maintenance dosage of lamotrigine of as much as twice the recommended target maintenance dose. Conversely, stopping estrogen-containing oral contraceptives, including during the “pill-free” week, may increase lamotrigine levels to a clinically significant range.

---

## Conclusion

---

Although initial results from trials of lamotrigine in the treatment of mania were unfavorable, subsequent maintenance studies have provided compelling data to show that lamotrigine prevents the recurrence of mood episodes and possesses antidepressant efficacy, albeit most convincingly for prophylaxis against depression recurrence as opposed to acute resolution of depression. Even with its ability to stabilize mood, lamotrigine appears to have a low propensity to trigger affective switches to mania or hypomania, with a switch risk similar to that of placebo. Lamotrigine’s neutral effects on body weight and favorable side-effect profile make it appealing for use in patients who have comorbid metabolic syndrome or those who are unable to tolerate other treatments. At present, lamotrigine remains the only antiepileptic drug mood stabilizer with more established efficacy in the depressed illness phase than in mania or hypomania.

# CHAPTER 41

## Topiramate

Susan L. McElroy, M.D.

Paul E. Keck Jr., M.D.

---

### History and Discovery

---

Topiramate was approved by the U.S. Food and Drug Administration (FDA) for the treatment of epilepsy in 1996, for migraine prevention in 2004, and in combination with phentermine for chronic weight management in 2012. Reports appearing in the late 1990s of the drug having potential beneficial effects in bipolar disorder led Johnson & Johnson Pharmaceutical Research and Development, the discoverer and manufacturer of topiramate, to conduct a large clinical study program of topiramate in the treatment of acute bipolar mania ([McElroy and Keck 2004](#)). Controlled trials of the drug in adults with manic or mixed symptoms of bipolar disorder failed to demonstrate significant separation between the topiramate and placebo groups ([Kushner et al. 2006](#); [Roy Chengappa et al. 2006](#)). However,

topiramate has been shown in placebo-controlled trials to be efficacious in several neuropsychiatric conditions often comorbid with bipolar disorder, including binge-eating disorder, bulimia nervosa, alcohol use disorder, borderline personality disorder, psychotropic-associated weight gain, and obesity, in addition to migraine headache. Additionally, mounting evidence suggests that topiramate augmentation of antipsychotic therapy may reduce psychological symptoms in schizophrenia spectrum disorders.

---

## Pharmacological Profile

---

Topiramate ([Figure 41-1](#)) has multiple pharmacological properties that may contribute to its anticonvulsant and neuropsychiatric effects ([Langtry et al. 1997](#); [Rho and Sankar 1999](#); [Rosenfeld 1997](#); [Shank et al. 2000](#); [White 2002, 2005](#); [White et al. 2007](#)). First, topiramate inhibits voltage-gated sodium channels in a voltage-sensitive, use-dependent manner and thus suppresses action potentials associated with sustained repetitive cell firing ([Kawasaki et al. 1998](#); [Shank et al. 2000](#)). Second, topiramate increases brain  $\gamma$ -aminobutyric acid (GABA) levels, possibly by activating a site on the GABA<sub>A</sub> receptor, thereby enhancing the inhibitory chloride ion influx mediated by the GABA<sub>A</sub> receptor and potentiating GABA-evoked currents ([Kuzniecky et al. 1998](#); [Petroff et al. 2001](#); [Simeone et al. 2006](#)). Because this action is not blocked by the benzodiazepine antagonist flumazenil, it is thought that topiramate exerts this effect via an interaction with the GABA<sub>A</sub> receptor that is not modulated by benzodiazepines ([White et al. 2000](#)).

---

**FIGURE 41-1.** Chemical structure of topiramate.

Third, topiramate antagonizes glutamate receptors of the  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA)/kainate subtype and may selectively inhibit glutamate receptor 5 (GluR<sub>5</sub>) kainate receptors ([Kaminski et al. 2004](#)). It has essentially no effect on glutamate *N*-methyl-D-aspartate (NMDA) receptors. AMPA/kainate receptors mediate fast excitatory postsynaptic potentials responsible for excitatory neurotransmission; blockade of kainate-evoked currents decreases neuronal excitability.

Fourth, topiramate negatively modulates high-voltage-activated calcium channels ([Zhang et al. 2000](#)). Of note, [Shank et al. \(2000\)](#) proposed that topiramate's combined effects on voltage-activated sodium channels, GABA<sub>A</sub> receptors, AMPA/kainate receptors, and high-voltage-activated calcium channels are unique as compared with those of other antiepileptic drugs. Indeed, [Schiffer et al. \(2001\)](#) found that pretreatment with topiramate inhibited nicotine-induced increases in mesolimbic extracellular dopamine and norepinephrine, but not serotonin. They hypothesized that this property was a result of the drug's ability to affect both GABAergic and glutamatergic function.

Fifth, topiramate weakly inhibits some carbonic anhydrase isoenzymes, including subtypes II and VI. Carbonic anhydrase is essential for the generation of GABA<sub>A</sub>-mediated depolarizing responses. By inhibiting carbonic anhydrase, topiramate has been shown to reversibly reduce the GABA<sub>A</sub>-mediated depolarizing responses evoked by either synaptic stimulation or pressure application of GABA (but not to modify GABA<sub>A</sub>-mediated hyperpolarizing postsynaptic potentials) ([Herrero et al. 2002](#)).

Finally, topiramate has a number of other properties. These include an interaction with glycine receptor channels ([Mohammadi et al. 2005](#)), effects on mitochondrial permeability ([Kudin et al. 2004](#)), and antikindling properties in some animal models ([Wauquier and Zhou 1996](#)).

---

## Pharmacokinetics and Disposition

---

Topiramate has a favorable pharmacokinetic profile ([Bialer et al. 2004](#); [Doose and Streeter 2002](#); [Langtry et al. 1997](#); [Rosenfeld 1997](#); [Shank et al. 2000](#)). It is rapidly and almost completely absorbed after oral administration, with bioavailability estimated to be about 80%. Peak plasma concentrations are reached within 2–4 hours. Plasma concentration increases in proportion to dose over the pharmacologically relevant dose range. Topiramate is minimally protein bound (9%–17%).

Topiramate is minimally metabolized by the liver in the absence of hepatic enzyme-inducing drugs. It inhibits cytochrome P450 (CYP) enzyme 2C19 but not other hepatic CYP enzymes. Topiramate is excreted mostly unchanged (approximately 70%) in the urine. The nonrenal (hepatic) clearance of topiramate increases two- to threefold when the drug is administered with hepatic enzyme-inducing drugs such as carbamazepine and phenytoin. Six minor metabolites have been identified ([Shank et al. 2000](#)).

Topiramate's elimination half-life is 19-25 hours, with linear pharmacokinetics in the dose range of 100-1,200 mg. The pharmacokinetics of topiramate in children are similar to those in adults, except that clearance is 50% higher, resulting in 33% lower plasma concentrations. Moderate or severe renal failure is associated with reduced renal clearance and increased elimination half-life of topiramate. Moderate or severe liver impairment is associated with clinically insignificant increased plasma concentrations of the drug.

---

## Mechanism of Action

---

Although the mechanism of topiramate's anticonvulsant action is unknown, it has been hypothesized to be due to some combination of the drug's multiple pharmacological properties ([Rho and Sankar 1999](#); [Shank et al. 2000](#); [White 2002, 2005](#); [White et al. 2007](#)). For example, the drug's anticonvulsant profile, as well as its benefits in substance use and eating disorders, has been hypothesized to be due to its dual actions on the GABAergic and glutamatergic

systems ([Johnson et al. 2003, 2005](#); [McElroy et al. 2003, 2007](#); [Rho and Sankar 1999](#); [Schiffer et al. 2001](#)).

---

## Indications and Efficacy

---

### FDA-Approved Indications

Topiramate is indicated by the FDA as initial monotherapy in patients ages 10 years and older with partial-onset or primary generalized tonic-clonic seizures; as adjunctive therapy for adults and for pediatric patients ages 2–16 years with partial-onset seizures or primary generalized tonic-clonic seizures; and in patients ages 2 years and older with seizures associated with Lennox-Gastaut syndrome ([van Passel et al. 2006](#)). Topiramate is also approved for the prophylaxis of migraine headache in adults ([Brandes 2005](#); [Bussone et al. 2006](#)). In 2012, the FDA approved topiramate extended release in combination with phentermine (marketed under the trade name Qsymia [[Vivus 2014](#)]) for chronic weight management as an adjunct to lifestyle modification in people who are obese (body mass index [BMI]  $\geq 30$  mg/kg) or who are overweight (BMI  $\geq 27$  mg/kg) and also have at least one weight-related comorbidity (e.g., hypertension, type 2 diabetes mellitus) ([Alfaris et al. 2015](#)).

### Other Indications

Topiramate is not approved by the FDA for use in the treatment of any psychiatric disorder. Because the drug

was widely used off-label in the treatment of bipolar disorder after it came to market (see subsection “Bipolar Disorder” below), Johnson & Johnson Pharmaceutical Research and Development, the discoverer of topiramate, conducted a large study program of topiramate in adults with acute bipolar mania. These placebo-controlled studies failed to demonstrate significant benefit from topiramate versus placebo on Young Mania Rating Scale (YMRS) scores ([Kushner et al. 2006](#); [McElroy and Keck 2004](#)). By contrast, findings from randomized, placebo-controlled trials suggest that topiramate may be efficacious in major depressive disorder, schizophrenia, binge-eating disorder (BED), bulimia nervosa, alcohol use disorder, psychotropic-induced weight gain, and obesity.

## **Bipolar Disorder**

Five randomized, placebo-controlled studies have shown that topiramate monotherapy is not efficacious in the short-term treatment of acute manic or mixed episodes in adults with bipolar I disorder ([Kushner et al. 2006](#); [McElroy and Keck 2004](#)). All five studies used week 3 as the primary endpoint; in addition, three of the studies had a week 12 secondary endpoint, two studies had lithium comparator groups, and all trials measured weight as a secondary outcome. In each trial, the primary efficacy outcome—the change from baseline to week 3 in the YMRS score—failed to show a statistically significant separation between topiramate and placebo. There was also no drug-versus-placebo separation in the three trials with week 12 data. By contrast, in the two trials in which lithium was used, lithium did show statistical superiority to placebo.

Similarly, in the only placebo-controlled study of adjunctive topiramate in bipolar disorder, 287 outpatients

experiencing a manic or mixed episode (by DSM-IV [[American Psychiatric Association 1994](#)] criteria) and a YMRS score of 18 or higher while taking therapeutic levels of valproate or lithium showed similar reductions (40%) in baseline YMRS scores for both topiramate and placebo after 12 weeks ([Roy Chengappa et al. 2006](#)). In the only placebo-controlled study of topiramate in pediatric bipolar I disorder, 56 children and adolescents (ages 6–17 years) experiencing a manic or mixed episode were randomly assigned to topiramate or placebo for 4 weeks ([DelBello et al. 2005](#)). Initially designed to enroll approximately 230 subjects, the study was prematurely discontinued when results from the adult mania trials were negative. Decrease in mean YMRS score from baseline to final visit using last observation carried forward (LOCF) analysis was not statistically different between treatment groups. However, a post hoc repeated-measures linear regression model of the primary efficacy analysis showed a statistically significant difference in the slopes of the linear mean profiles ( $P=0.003$ ).

No placebo-controlled study of topiramate has yet been done in acute bipolar depression. Results from an 8-week single-blind comparison trial in which 36 outpatient adults with bipolar depression were randomly assigned to receive either topiramate (mean dosage=176 mg/day; range=50–300 mg/day) or bupropion sustained release (mean dosage=250 mg/day; range=100–400 mg/day) suggested that the drug might have antidepressant properties in some bipolar patients ([McIntyre et al. 2002](#)). The percentage of patients meeting a priori response criteria ( $\geq 50\%$  decrease from baseline in mean total score on the 17-item Hamilton Rating Scale for Depression [Ham-D]) was significant for

both topiramate (56%) and bupropion sustained release (59%).

## Depressive Disorders

Two randomized, placebo-controlled studies of topiramate in patients with major depressive disorder have been conducted. In the first, 64 females with DSM-IV recurrent major depressive disorder were randomly assigned to receive topiramate or placebo for 10 weeks ([C. Nickel et al. 2005a](#)). Topiramate was superior to placebo in reducing depressive and anger symptoms. All subjects tolerated topiramate well, and there were no suicidal events. In the second study, 53 patients with DSM-IV major depressive disorder that had been inadequately responsive to an 8-week trial of a selective serotonin reuptake inhibitor (SSRI) were randomly assigned to receive adjunctive topiramate (100–200 mg/day) or placebo for 8 weeks ([Mowla and Kardeh 2011](#)). Topiramate recipients had a 32% mean decrease in Ham-D score, whereas placebo recipients had a mean decrease of 5.5%. Topiramate augmentation also produced significantly greater global improvement in depressive symptoms compared with placebo augmentation. Six patients discontinued topiramate because of side effects, which included loss of appetite, gastric disturbance, memory problems, and akathisia. No suicidal events were reported.

## Psychotic Disorders

**Studies.** Seven randomized, placebo-controlled studies of topiramate targeting psychopathology in patients with psychotic disorders have been conducted, with mixed results. Six of these studies involved patients with

schizophrenia, and one involved patients with schizoaffective disorder, bipolar type.

*Schizophrenia.* In the first schizophrenia study, 26 patients with treatment-resistant illness had topiramate (gradually increased to 300 mg/day) or placebo added to their ongoing antipsychotic regimens over two 12-week crossover treatment periods ([Tiihonen et al. 2005](#)). In the intent-to-treat analysis, topiramate was superior to placebo in reducing general psychopathological symptoms as assessed by the Positive and Negative Syndrome Scale (PANSS), but no significant improvement was observed in positive or negative symptoms.

In the second study, 66 inpatients with schizophrenia who were being treated with risperidone were randomly assigned to receive augmentation with topiramate 100 mg/day, topiramate 200 mg/day, or placebo for 12 weeks ([Ko et al. 2005](#)). Both dosages of topiramate were superior to placebo in reducing psychopathology, as assessed with the Clinical Global Impressions (CGI) Severity of Illness subscale (CGI-S) and the Brief Psychiatric Rating Scale (BPRS).

In the third study, either topiramate (up to 300 mg/day) or placebo was added to the clozapine regimens of 32 patients with schizophrenia for 56 days ([Afshar et al. 2009](#)). At day 56, total PANSS values, as well as scores for all three subscales (negative symptoms, positive symptoms, and general psychopathology), were significantly improved in the topiramate-augmentation group compared with the placebo-augmentation group.

In the fourth study, 72 drug-naïve patients with schizophrenia were randomly assigned to receive olanzapine plus topiramate 100 mg/day or olanzapine plus

placebo for 12 weeks ([Narula et al. 2010](#)). Compared with the placebo-treated group, the topiramate-treated group showed significantly greater improvement on PANSS total scores ( $P=0.001$ ) and general psychopathology measures ( $P<0.001$ ).

In the fifth study, 43 patients with treatment-resistant schizophrenia who were receiving clozapine were given adjunctive topiramate (up to 200 mg/day) or placebo for 24 weeks ([Muscatello et al. 2011](#)). The addition of topiramate was associated with a significant reduction in bizarre behavior as assessed on the Scale for the Assessment of Positive Symptoms (SAPS) ( $P<0.002$ ); however, no significant improvement in positive, negative, affective, or overall clinical symptomatology was otherwise seen with topiramate.

In the sixth study, either topiramate (200–300 mg/day) or placebo was added to clozapine in 80 hospitalized patients with schizophrenia for 17 weeks ([Behdani et al. 2011](#)). At endpoint, add-on topiramate was not superior to add-on placebo in reducing positive, negative, or general psychopathological symptoms as assessed by the PANSS.

*Schizoaffective disorder.* In the schizoaffective disorder study, 48 patients with a diagnosis of DSM-IV schizoaffective disorder, bipolar type, were randomly assigned in a 2:1 ratio (favoring topiramate) to 8 weeks of double-blind treatment with topiramate (100–400 mg/day) or placebo ([Roy Chengappa et al. 2007](#)). Patients who had achieved at least a 20% decrease from baseline in their PANSS total scores were given the opportunity to continue for an additional 8 weeks of double-blind treatment. Adjunctive topiramate (nearly 275 mg/day) did not show increased efficacy relative to placebo on the PANSS (the

primary outcome measure) or on any of the secondary outcome measures.

**Case reports.** There are several case reports of the successful use of topiramate to treat catatonia in patients with chronic psychotic disorders ([McDaniel et al. 2006](#)). By contrast, there are also reports of the emergence of psychotic symptoms with topiramate treatment ([Duggal and Singh 2004](#); [Miller et al. 2010](#)).

## Eating Disorders

Five positive randomized, placebo-controlled studies involving subjects with bulimia nervosa (two studies) or BED (three studies) have demonstrated that topiramate reduces binge eating.

**Bulimia nervosa.** In the first bulimia nervosa study, a 10-week trial with 69 subjects, topiramate (median dosage=100 mg/day; range=25–400 mg/day) was superior to placebo in reducing the frequency of binge and purge days (days during which at least one binge-eating or purging episode occurred;  $P=0.004$ ) ([Hedges et al. 2003](#); [Hoopes et al. 2003](#)). Binge-eating/purging remission rates were 32% for topiramate and 6% for placebo ( $P=NS$ ). Dropout rates were 34% for topiramate and 47% for placebo. In the second study, subjects with DSM-IV bulimia nervosa received 10 weeks of topiramate (titrated to 250 mg/day in the sixth week) ( $n=30$ ) or placebo ( $n=30$ ) ([C. Nickel et al. 2005b](#)). Topiramate was associated with significant decreases in binge/purge frequency (defined as a >50% reduction; 37% for topiramate and 3% for placebo), body weight (difference in weight loss between

the two groups=3.8 kg), and all of the Short Form 36-Item Health Survey (SF-36) scales (all  $P$ s < 0.001).

**Binge-eating disorder.** In the first controlled study in BED, 61 subjects with DSM-IV BED and obesity received topiramate or placebo for 14 weeks ([McElroy et al. 2003](#)). Topiramate was significantly superior to placebo in reducing binge frequency, as well as global severity of illness, obsessive-compulsive features of binge-eating symptoms, body weight, and BMI. The dropout rate, however, was high: 14 (47%) subjects receiving topiramate and 12 (39%) subjects receiving placebo did not complete the trial.

The second controlled study of topiramate in BED was a multicenter trial in which subjects with DSM-IV BED and at least three binge-eating days per week, a BMI ranging from 30 kg/m<sup>2</sup> to 50 kg/m<sup>2</sup>, and no current psychiatric disorders or substance abuse were randomly assigned to receive topiramate or placebo for 16 weeks ([McElroy et al. 2007](#)). Of 407 subjects enrolled, 13 did not meet inclusion criteria; 195 topiramate and 199 placebo subjects were therefore evaluated for efficacy. Topiramate significantly reduced binge-eating days per week, binge episodes per week, weight, and BMI compared with placebo (all  $P$ s < 0.001). The drug also significantly decreased measures of obsessive-compulsive symptoms, impulsivity, hunger, and disability. Fifty-eight percent of topiramate-treated subjects achieved remission compared with 29% of placebo-treated subjects ( $P$  < 0.001). Discontinuation rates were 30% in each group; adverse events were the most common reason for topiramate discontinuation (16%; placebo, 8%).

The third controlled study of topiramate in BED was another multicenter trial in which 73 patients with BED and

obesity were randomly assigned to 19 sessions of cognitive-behavioral therapy (CBT) in conjunction with topiramate or placebo for 21 weeks ([Claudino et al. 2007](#)). Compared with patients given placebo, patients given topiramate showed a significantly greater rate of reduction in weight, the primary outcome measure, over the course of treatment ( $P<0.001$ ). Topiramate recipients also showed a significant weight loss ( $-6.8$  kg) relative to placebo recipients ( $-0.9$  kg). A greater percentage of topiramate-treated patients (31 of 37) than of placebo-treated patients (22 of 36) attained remission of binge eating ( $P=0.03$ ). There was no difference between groups in completion rates, although one topiramate recipient withdrew because of an adverse effect.

**Other eating disorders.** There are no randomized controlled studies of topiramate in anorexia nervosa. However, there are reports of topiramate triggering or worsening anorexia nervosa as well as reports of eating disorder patients misusing the drug to lose weight ([McElroy et al. 2008](#)). In contrast, there are case reports of the successful treatment of night eating syndrome with topiramate ([Kucukgoncu et al. 2015](#)).

## **Substance-Related and Addictive Disorders**

Growing evidence suggests that topiramate may have therapeutic effects in some substance-related and addictive disorders, especially alcohol use disorder.

**Alcohol use disorder.** At least eight studies examined topiramate in alcohol use disorder. In the first, 150 subjects with DSM-IV alcohol dependence were randomly assigned to receive topiramate (up to 300 mg/day) or placebo for 12

weeks ([Johnson et al. 2003](#)). All subjects also received compliance enhancement therapy. At study end, subjects receiving topiramate, compared with those receiving placebo, had significantly fewer drinks per day ( $P=0.0006$ ), fewer drinks per drinking day ( $P=0.0009$ ), fewer heavy drinking days ( $P=0.0003$ ), more days abstinent ( $P=0.0003$ ), and a log plasma  $\gamma$ -glutamyl transferase (GGT) ratio of 0.07 less ( $-0.11$  to  $-0.02$ ) ( $P=0.0046$ ). Craving was also significantly more improved with topiramate than with placebo.

In the second study, 371 subjects with DSM-IV alcohol dependence were randomly assigned to receive topiramate (up to 300 mg/day) or placebo, along with a weekly compliance enhancement intervention, at 16 sites for 14 weeks ([Johnson et al. 2007](#)). Topiramate was significantly superior to placebo in reducing the percentage of heavy drinking days and other drinking outcomes such as drinks per drinking day, increasing the percentage of days abstinent, and improving the log plasma GGT ratio (all  $P_s \leq 0.002$ ).

In the third study, 155 subjects with DSM-IV alcohol dependence who had been detoxified for 1 week were randomized to receive topiramate (up to 300 mg/day), naltrexone, or placebo in addition to relapse prevention counseling and encouragement to participate in Alcoholics Anonymous for 12 weeks ([Baltieri et al. 2008](#)). Topiramate was superior to placebo on a number of measures, including time to first relapse, cumulative abstinence duration, weeks of heavy drinking, and percentage of subjects abstinent, at 4 weeks and 8 weeks, but not at 12 weeks. There were no significant differences between naltrexone versus placebo or between topiramate versus naltrexone.

In the fourth study, 63 patients with DSM-IV alcohol dependence were randomly assigned to receive topiramate or placebo for 12 weeks ([Rubio et al. 2009](#)). Compared with placebo recipients, topiramate recipients had significantly lower numbers of drinks per drinking day ( $P<0.05$ ) and of heavy drinking days ( $P<0.001$ ).

In the fifth study, 170 subjects with comorbid DSM-IV alcohol and cocaine dependence who had attained baseline abstinence were randomly assigned to receive topiramate (300 mg/day) or placebo in addition to weekly psychotherapy for 13 weeks ([Kampman et al. 2013](#)). Topiramate was not superior to placebo in reducing cocaine or alcohol use.

In the sixth study, 106 patients with DSM-IV alcohol dependence receiving residential treatment were randomly assigned to topiramate (100–300 mg/day) or placebo for 12 weeks ([Likhitsathian et al. 2013](#)). No significant differences between the two groups were found in mean percentages of heavy drinking days or time to first day of heavy drinking.

In the seventh study, 138 individuals with heavy drinking (most of whom met criteria for DSM-IV alcohol dependence) were randomly assigned to receive topiramate (titrated to 100 mg twice daily) or placebo for 12 weeks ([Kranzler et al. 2014](#)). Compared with placebo, topiramate significantly reduced heavy drinking days and increased abstinent days ( $P=0.001$  and  $0.03$ , respectively). Moreover, a single-nucleotide polymorphism (rs2832407) in *GRIK1*, which encodes for the kainite GluK1 receptor subunit, may have moderated topiramate's effect on heavy drinking. Specifically, topiramate's effect on heavy drinking days was significantly greater than that of placebo only in participants who were rs2832407 C-allele homozygotes.

In the eighth study, 85 participants with DSM-IV alcohol dependence were randomly assigned to receive topiramate, zonisamide, levetiracetam, or placebo for 14 weeks (including a 2-week taper period) ([Knapp et al. 2015](#)). Both topiramate and zonisamide produced significant reductions in drinking behavior. However, whereas topiramate and zonisamide both were associated with modest reductions in verbal fluency and working memory, only topiramate produced a significant increase in mental slowing,

**Cocaine use disorder.** Five randomized, placebo-controlled trials have evaluated topiramate in DSM-IV cocaine dependence, with mixed results. In the first study, 40 cocaine-dependent individuals were randomly assigned to topiramate (titrated gradually over 8 weeks to 200 mg/day) or placebo for 13 weeks ([Kampman et al. 2004](#)). Topiramate-treated subjects were more likely than placebo-treated subjects to be abstinent from cocaine after week 8 ( $P=0.01$ ). They were also more likely to achieve 3 weeks of continuous abstinence from cocaine ( $P=0.05$ ).

In the second study, 81 cocaine-dependent subjects were randomly assigned to receive topiramate (titrated to 150 mg twice daily) plus mixed amphetamine salts or placebo for 12 weeks ([Mariani et al. 2012](#)). The proportion of patients achieving 3 weeks of abstinence was larger for active drug treatment (33.3%) than for placebo (16.7%). Combination treatment may have been more effective in subjects with a high baseline frequency of cocaine use.

In the third study, 142 patients with DSM-IV cocaine dependence were randomly assigned to receive topiramate (target maintenance dosage=300 mg/day) or placebo in combination with CBT for 12 weeks ([Johnson et al. 2013](#)). Topiramate was more efficacious than placebo at increasing

the weekly proportion of nonuse days, and also was associated with significantly more urinary cocaine-free weeks, decreased craving, and improved global functioning.

In the fourth trial, 170 subjects with comorbid DSM-IV cocaine and alcohol dependence were randomly assigned to receive topiramate 300 mg/day or placebo for 13 weeks ([Kampman et al. 2013](#)). Topiramate was not superior to placebo for reducing cocaine or alcohol use.

In the fifth study, 171 cocaine-dependent patients undergoing methadone maintenance treatment were randomly assigned to receive topiramate or placebo in addition to monetary voucher incentives that were either contingent or noncontingent on drug abstinence for 15 weeks (including 8 weeks at a maintenance dosage of 300 mg/day) ([Umbricht et al. 2014](#)). There were no significant differences between the topiramate and placebo conditions, or between the contingent and noncontingent incentive conditions. Additionally, there were no topiramate-contingency interactions, and topiramate was associated with cognitive impairment.

**Methamphetamine use disorder.** Two randomized controlled trials have assessed topiramate in DSM-IV methamphetamine addiction. In the first study, 140 methamphetamine-addicted subjects were randomly assigned to receive topiramate (target maintenance dosage=200 mg/day) or placebo for 13 weeks ([Elkashef et al. 2012](#)). Topiramate did not increase abstinence from methamphetamine over weeks 6-12 of treatment (the primary outcome measure). On secondary outcomes, however, topiramate reduced weekly median urine methamphetamine levels and overall severity of dependence scores ( $P=0.03$  for both).

In the second study, 62 adults with DSM-IV methamphetamine dependence were randomly assigned to receive topiramate (up to 200 mg/day) or placebo for 10 weeks ([Rezaei et al. 2016](#)). At week 6, compared with the placebo group, the topiramate group had a significantly lower proportion of methamphetamine-positive urine tests ( $P=0.01$ ). The topiramate-treated subjects also had lower scores on the drug use severity and drug need items of the Addiction Severity Index (ASI) (both  $P$ s<0.001).

**Smoking cessation.** Three randomized controlled trials have assessed topiramate in smoking cessation. In the first study, topiramate was superior to placebo in 94 subjects with comorbid DSM-IV alcohol dependence ([Johnson et al. 2003](#)). This study was a subgroup analysis of the first controlled study of topiramate in alcohol dependence ([Johnson et al. 2003](#)). In the second study, topiramate was superior to placebo for smoking cessation in male ( $n=38$ ) but not female ( $n=49$ ) subjects who had no associated psychopathology ([Anthenelli et al. 2008](#)). In the third study, which followed a placebo-controlled trial in 155 male outpatients with ICD-10 ([World Health Organization 1993](#)) alcohol dependence ([Baltieri et al. 2008](#)), a subset of the alcoholic participants who were smokers ( $n=103$ ) were randomly assigned to receive topiramate, naltrexone, or placebo for 12 weeks ([Baltieri et al. 2009](#)). Whereas naltrexone did not separate from placebo, topiramate was found to be more effective than placebo in reducing the number of cigarettes smoked.

**Gambling disorder.** One 14-week placebo-controlled trial assessed topiramate in 42 patients with DSM-IV pathological gambling ([Berlin et al. 2013](#)). There were no

significant treatment effects of topiramate on the primary (Y-BOCS Modified for Pathological Gambling) or any secondary outcome measures.

## **Posttraumatic Stress Disorder**

Topiramate has been evaluated in three placebo-controlled studies of posttraumatic stress disorder (PTSD). In the first study, 38 civilian patients with PTSD were randomly assigned to flexible dosages of topiramate alone (median dosage=150 mg/day) or placebo for 12 weeks ([Tucker et al. 2007](#)). No significant difference between topiramate and placebo was found on the primary efficacy measure, change in total Clinician-Administered PTSD Scale (CAPS) score. However, significant or near-significant effects in favor of topiramate were observed on the eight-item Treatment Outcome PTSD scale (TOP-8) score (decrease in overall severity of 68% for topiramate vs. 42% for placebo;  $P=0.025$ ) and the endpoint CGI Improvement subscale (CGI-I) score ( $1.9\pm1.2$  vs.  $2.6\pm1.1$ ;  $P=0.055$ ).

In the second study, 40 male veterans with chronic PTSD, most of whom were receiving antidepressants, were given topiramate (up to 200 mg/day) or placebo for 7 weeks ([Lindley et al. 2007](#)). No significant drug-versus-placebo difference was found for the primary outcome measures (CAPS, CGI-S, or Patient Global Impression of Improvement Scale [PGI-I] scores).

In the third study, 30 veterans with PTSD and a co-occurring alcohol use disorder were randomly assigned to receive topiramate (up to 300 mg/day) or placebo for 12 weeks ([Batki et al. 2014](#)). Compared with placebo, topiramate tended to reduce the primary outcome measure—frequency of drinking days ( $P=0.063$ )—but not measures of PTSD symptoms.

## Obsessive-Compulsive Disorder

Four placebo-controlled trials have evaluated adjunctive topiramate in subjects with obsessive-compulsive disorder (OCD), with mixed results. In the first study, 41 subjects with OCD that had not improved after at least 12 weeks of treatment with an SSRI were randomly assigned to receive topiramate or placebo plus their current OCD regimen for 12 weeks. Topiramate recipients had a mean decrease of 32% in Yale-Brown Obsessive Compulsive Scale (Y-BOCS) scores, whereas placebo recipients had a decrease of 2.4% ([Mowla et al. 2010](#)). In the second study, adjunctive topiramate (mean endpoint dosage 179 mg/day) significantly reduced the Y-BOCS Compulsions subscale score ( $P=0.014$ ), but not the Obsessions subscale score or the total score, in 36 adult subjects with OCD receiving SSRIs ([Berlin et al. 2011](#)). In the third study, 39 inpatients with OCD and bipolar mania were randomly assigned to receive the addition of topiramate or placebo to their current regimen of lithium, olanzapine, and clonazepam was associated with significantly for 4 months ([Sahraian et al. 2014](#)). Y-BOCS scores showed a greater numeric decline for patients receiving placebo than for those receiving topiramate. By contrast, among the 32 completers, there were significantly more responders (defined as >34% reduction in Y-BOCS scores) among topiramate recipients than among placebo recipients (53% and 12.5%, respectively;  $P<0.01$ ). However, in the fourth study, involving 38 patients with refractory OCD, topiramate (mean dosage=137.5 mg/day) was not superior to placebo in reducing Y-BOCS scores after 12 weeks of treatment ([Afshar et al. 2014](#)).

## Borderline Personality Disorder

Three placebo-controlled studies, all conducted by the same group, have evaluated topiramate in DSM-IV-defined borderline personality disorder. In the first study, 29 female subjects were randomly assigned in a 2:1 ratio to topiramate or placebo for 8 weeks ([Nickel et al. 2004](#)). Topiramate dosage was increased to 250 mg/day over 6 weeks. At study end, significant improvement on four subscales of the State-Trait Anger Expression Inventory (STAXI)—state-anger, trait-anger, anger-out, and anger-control—was observed for topiramate compared with placebo.

In the second study, 42 male subjects with borderline personality disorder received topiramate or placebo for 8 weeks (M.K. [Nickel et al. 2005a](#)). Similar to the study in females, significant improvement on the same four STAXI subscales was found for topiramate compared with placebo.

In the third study, 56 women with borderline personality disorder received topiramate or placebo for 10 weeks ([Loew et al. 2006](#)). Topiramate was titrated to 200 mg/day over 6 weeks and then held constant. Topiramate was superior to placebo on the somatization, interpersonal sensitivity, anxiety, hostility, phobic anxiety, and Global Severity Index subscales of the Symptom Checklist-90—Revised (SCL-90-R) (all  $P$ s<0.001), all eight scales of the SF-36 (all  $P$ s<0.01), and four of eight scales of the Inventory of Interpersonal Problems (all  $P$ s<0.001). In all three studies, topiramate was well tolerated, and there were no psychotic or suicidal adverse events.

## Psychotropic Medication-Associated Weight Gain

At least four placebo-controlled studies have suggested that topiramate reduces antipsychotic-related weight gain in patients with psychotic or mood disorders. In one study, 66 inpatients with schizophrenia receiving antipsychotic medication and “carrying excess weight” were randomly assigned to receive topiramate 100 mg/day, topiramate 200 mg/day, or placebo for 12 weeks ([Ko et al. 2005](#)). Body weight, BMI, and waist and hip circumferences decreased significantly in the topiramate 200 mg/day group compared with the topiramate 100 mg/day and placebo groups.

In another study, 43 women with mood or psychotic disorders who had gained weight while receiving olanzapine were given topiramate or placebo for 10 weeks ([M.K. Nickel et al. 2005b](#)). Weight loss was significantly greater (by 5.6 kg) in the topiramate group. Topiramate-treated subjects also experienced significantly greater improvement in measures of health-related quality of life and psychological impairment.

In a third study, topiramate as an adjunct to lithium or valproate treatment was ineffective for manic symptoms in patients with bipolar I disorder experiencing a manic or mixed episode but was associated with significantly greater reductions in body weight compared with placebo (−2.5 and 0.2 kg, respectively;  $P<0.001$ ) and in BMI (−0.84 and 0.07 kg/m<sup>2</sup>, respectively;  $P<0.001$ ) ([Roy Chengappa et al. 2006](#)).

In a fourth study, adjunctive topiramate was evaluated for utility in prevention of olanzapine-related weight gain ([Narula et al. 2010](#)). In this 12-week trial, 72 patients with schizophrenia were randomly assigned to receive olanzapine plus topiramate 100 mg or olanzapine plus placebo. Whereas topiramate augmentation was associated with statistically significant weight loss, placebo-augmented

olanzapine was associated with significant weight gain ( $P=0.05$  between-group difference). Topiramate augmentation was also associated with significantly greater improvement in several metabolic variables, systolic and diastolic blood pressure, and PANSS General Psychopathology Scale and total scores.

## Obesity

At least nine randomized, placebo-controlled trials have evaluated topiramate ([Astrup et al. 2004](#); [Bray et al. 2003](#); [Eliasson et al. 2007](#); [Stenlöf et al. 2007](#); [Tonstad et al. 2005](#); [Toplak et al. 2007](#); [Tremblay et al. 2007](#); [Wilding et al. 2004](#)) or a controlled-release formulation of topiramate ([Rosenstock et al. 2007](#)) for weight loss in subjects with obesity. In all nine studies, topiramate was superior to placebo for weight loss at all dosages (range=64–400 mg/day) and at all endpoints (ranging from 28 weeks to 1 year) evaluated. The four long-term studies (duration ranging from 40 weeks to 1 year) found that topiramate was associated with weight loss that continued for up to 1 year without plateauing ([Astrup et al. 2004](#); [Eliasson et al. 2007](#); [Stenlöf et al. 2007](#); [Wilding et al. 2004](#)). In a study of subjects with comorbid obesity and hypertension, there were significant decreases in diastolic but not systolic blood pressure in the two groups receiving topiramate (either 96 mg/day or 192 mg/day) compared with the placebo group ([Tonstad et al. 2005](#)). In four studies of topiramate in subjects with comorbid obesity and type 2 diabetes, topiramate-treated subjects showed significant decreases in glycosylated hemoglobin ( $Hb_{A1c}$ ) compared with placebo-treated subjects ([Eliasson et al. 2007](#); [Rosenstock et al. 2007](#); [Stenlöf et al. 2007](#); [Toplak et al. 2007](#)). In the pivotal

studies leading to the FDA approval of topiramate extended release plus phentermine for chronic weight management, topiramate monotherapy was superior to placebo for weight loss, and the drug combination was superior to either topiramate or phentermine monotherapy ([Alfaris et al. 2015](#)).

---

## Side Effects and Toxicology

---

The side-effect profile of topiramate may vary with the patient's illness, mood state, and concomitant medications.

### Common Side Effects

The most common side effects of topiramate in the initial dose-ranging studies in patients with epilepsy when used in combination with other antiepileptic drugs at dosages of 200–1,000 mg/day were related to the central nervous system and included dizziness, somnolence, psychomotor slowing, nervousness, paresthesias, ataxia, difficulty with memory, difficulty with concentration or attention, confusion, and speech disorders or related speech problems ([Langtry et al. 1997](#); [Shorvon 1996](#)). Other side effects were nystagmus, depression, nausea, diplopia, abnormal vision, anorexia, language problems, and tremor. When topiramate was used as monotherapy in patients with epilepsy, the most common side effects were dizziness, anxiety, paresthesias, insomnia, somnolence, myalgia, anorexia, nausea, dyspepsia, and diarrhea. The most common side effects of topiramate in the large registration trials for migraine headache (which used total daily dosages

of 50, 100, and 200 mg) were paresthesias, fatigue, memory difficulties, concentration/attention problems, and mood problems ([Bussone et al. 2006](#)). In the monotherapy trials in adult mania, paresthesias, decreased appetite, dry mouth, and weight loss were more common with topiramate than placebo ([Kushner et al. 2006](#)). In the obesity trials, events related to the central or peripheral nervous system or to psychiatric disorders were most commonly reported ([Rosenstock et al. 2007](#)). These included paresthesias; fatigue; difficulty with attention, concentration, and/or memory; taste perversion; and anorexia. Overall, paresthesias and cognitive complaints were the most troublesome adverse events ([van Passel et al. 2006](#)). A meta-analysis suggested that a dose-response relationship exists for dizziness, cognitive impairment, and fatigue ([Zaccara et al. 2008](#)).

The central nervous system and gastrointestinal effects of topiramate are usually mild to moderate in severity and often decrease or resolve with time or dosage reduction ([Meador et al. 2003](#); [Shorvon 1996](#)). Also, they may be minimized through slow titration of topiramate dosage ([Biton et al. 2001](#)). However, topiramate may be associated with more cognitive impairment than some of the other new antiepileptic drugs ([Martin et al. 1999](#); [Meador et al. 2003](#)).

## Infrequent Adverse Effects

Infrequent but serious side effects of topiramate include nephrolithiasis, an ocular syndrome of acute myopia with secondary angle-closure glaucoma, oligohydrosis and hyperthermia, and metabolic acidosis ([van Passel et al. 2006](#)). Mild hypokalemia, which usually is not clinically

significant, may also occur in about 10% of topiramate recipients ([Dell'Orto et al. 2014](#)).

The incidence of topiramate-associated nephrolithiasis has been estimated to be 1.5% ([Shorvon 1996](#)). In the epilepsy trials, more than 75% of the patients who developed renal stones elected to continue treatment with topiramate ([Reife et al. 2000](#)). Nephrolithiasis is thought to be related to topiramate's inhibition of carbonic anhydrase in the kidney ([Welch et al. 2006](#)).

The secondary angle-closure glaucoma associated with topiramate is characterized by acute onset of bilateral blurred vision and ocular pain ([Fraunfelder and Fraunfelder 2004](#); [Fraunfelder et al. 2004](#)). Ophthalmological findings include bilateral myopia, conjunctival hyperemia, anterior chamber shallowing, and increased intraocular pressure. Most cases have occurred within 1 month of topiramate initiation and fully resolve with drug discontinuation. Peripheral iridectomy and laser iridotomy are not effective. The syndrome has been attributed to sulfamate-induced ciliary body edema.

Oligohydrosis and hyperthermia occurring with topiramate can present as heat stroke or fever, may be related to exercise or high environmental temperature, can be fatal, is probably more common in children than in adults, and is reversible upon drug discontinuation ([Karachristianou et al. 2013](#)). Topiramate-induced metabolic acidosis is usually asymptomatic and associated with low bicarbonate, and to a lesser degree, increased chloride levels ([Dell'Orto et al. 2014](#); [Sciegienka et al. 2015](#)). Rarely, it presents with Kussmaul breathing or even altered mental status. It may be due to the carbonic anhydrase-inhibiting properties of topiramate, and it is also reversible upon drug discontinuation.

Because there were no clinically relevant changes in hepatic, renal, or hematological parameters in the registration trials of topiramate, laboratory monitoring was initially thought to be unnecessary ([Reife et al. 2000](#); [Sachdeo and Karia 2002](#)). In addition, no treatment-related changes were noted in physical or neurological examinations (except body weight loss), electrocardiograms, or ophthalmological or audiometric test results. However, because topiramate may cause metabolic acidosis and hypokalemia in some patients, it is now recommended that baseline and periodic serum bicarbonate and potassium levels be measured in patients receiving topiramate ([Dell'Orto et al. 2014](#); [Sachdeo and Karia 2002](#); [van Passel et al. 2006](#); [Welch et al. 2006](#)).

## Psychiatric Adverse Events

A growing concern is the psychiatric adverse-event profile of antiepileptic drugs in patients with epilepsy, including whether such drugs cause depression, suicidality, or psychosis. Thus, topiramate may be associated with depression in epilepsy patients, especially during rapid titration ([Mula and Sander 2007](#)). There are also isolated reports of topiramate's induction of mood and anxiety symptoms in psychiatric patients ([Damsa et al. 2006](#); [Klufas and Thompson 2001](#)). Moreover, one obesity study reported eight (6.2%) suicide-related events occurring in topiramate-treated subjects versus none in placebo-treated subjects ([Rosenstock et al. 2007](#)).

## Use in Pregnancy

Topiramate can cause fetal harm when given to pregnant women. Prenatal exposure to topiramate is associated with an increased risk of oral clefts ([Hunt et al. 2008](#)).

---

## Drug-Drug Interactions

---

The clearance of topiramate can be increased by the coadministration of hepatic enzyme-inducing drugs ([Bialer et al. 2004](#); [Gidal 2002](#); [Langtry et al. 1997](#); [Rosenfeld et al. 1997](#); [van Passel et al. 2006](#)). Thus, carbamazepine and phenytoin may substantially decrease topiramate levels.

Conversely, topiramate has mild enzyme-inducing properties and may enhance the metabolism of ethinyl estradiol. Available data suggest that at topiramate dosages of 200 mg/day or lower, this induction is insignificant, but at dosages greater than 200 mg/day, induction becomes dose dependent and occurs to a great extent ([Bialer et al. 2004](#)). Therefore, women taking combination oral contraceptive agents need to be counseled about this potential interaction.

Although there have been reports of topiramate causing increased lithium levels ([Abraham and Owen 2004](#)), this effect appears to be rarely clinically significant ([Bialer et al. 2004](#)).

---

## Conclusion

---

In sum, although topiramate does not have regulatory approval for a psychiatric disorder, considerable data suggest that the drug may be helpful in a wide range of

psychiatric conditions. In particular, topiramate appears efficacious in BED, bulimia nervosa, alcohol use disorder, and psychotropic-associated weight gain. It might also be efficacious for major depressive disorder, schizophrenia, and borderline personality disorder. Data on topiramate's efficacy in cocaine or methamphetamine use disorders, smoking cessation, and OCD have been mixed. Of note, there is no evidence to suggest that topiramate has acute anti-manic or long-term mood-stabilizing effects in bipolar disorder. The use of topiramate in psychiatric disorders, however, is limited by its adverse event profile.

# **Other Agents**

# CHAPTER 42

## Agents for Cognitive Disorders

Frank W. Brown, M.D.

Disruption of cholinergic neurotransmission and excitatory amino acids is correlated with the development of cognitive impairment and, specifically, Alzheimer's disease ([Mesulam 2004](#)). Multiple mechanisms exist that may account for the progression of cognitive impairment, including those related to cholinesterase, *N*-methyl-D-aspartate (NMDA), vascular disease, defective neurogenesis, and oxidative damage ([Aisen and Davis 1994](#); [Bartus et al. 1982](#); [Behl 1999](#); [Behl et al. 1992](#); [Crews and Masliah 2010](#); [Jick et al. 2000](#); [Kalaria et al. 1996](#); [Liu et al. 2015](#); [Selkoe 2000](#); [Terry and Buccafusco 2003](#); [Wolozin et al. 2000](#)). An outcome of the disruption of many neurotransmitter systems, cognitive impairment may occur at any time during the disease process as synaptic plasticity becomes impaired, degrading the efficiency of neuronal transmission ([Malik et al. 2007](#)). It is intuitive that the

earliest intervention prior to irreversible disease progression is optimal. Currently, it is unknown when the irreversible disease processes begin. The identification of specific markers that can guide clinicians in the initiation of prophylactic or abortive treatment prior to the development of cognitive or behavioral manifestations is highly desired. Continuing studies of circulating microRNAs in the cerebrospinal fluid and blood serum show promise as reliable biomarkers for early diagnosis of Alzheimer's disease (Kim et al. 2014). For early-onset autosomal dominant Alzheimer's disease, mutations in presenilin 1, presenilin 2, and amyloid precursor protein are known (Kim et al. 2014).

*Cognitive enhancer* is a general term that denotes a pharmacological or nutraceutical intervention that improves cognitive functioning in an impaired or normal brain by reversing or delaying underlying neuropathological changes within the brain or by modulating the existing neurochemistry to facilitate a desired performance differential. The molecular pathogenesis of cognitive impairment is not fully understood; thus, an ideal pharmacological agent has been difficult to develop. No single agent developed to date is ideally suited for this task; however, several agents have shown beneficial results. In this chapter, I review the established and the most promising potential cognitive enhancers.

---

## **Cholinesterase-Related Therapies**

---

Impairment of cholinergic neurotransmission, especially in the hippocampus and cerebral cortex (temporoparietal), has been clearly established over the past 40 years as a significant factor in the clinical signs of cognitive impairment, including those of Alzheimer's disease ([Davies and Maloney 1976](#); [Mesulam 2004](#); [Whitehouse et al. 1982](#)). Butyrylcholinesterase (BChE) and acetylcholinesterase (AChE) are the two main types of cholinesterase present in the brain. The development of AChE inhibitors (AChEIs) to increase acetylcholine levels in the brain for enhanced synaptic transmission has been successful, with marginal positive clinical outcomes to date ([Birks 2006](#); [Tan et al. 2014](#); [Thompson et al. 2004](#)). Four AChEIs have been marketed in the United States for cognitive therapy: tacrine, donepezil, rivastigmine, and galantamine. These pharmaceuticals are primarily for symptomatic relief and have limited current value in stopping or reversing the disease process. A significant number of AChEI nonresponders exist ([Jones 2003](#)). Improvements in cognitive functioning have been shown with AChEIs without major differences in their efficacy ([Birks 2006](#); [Colović et al. 2013](#); [Seltzer 2006](#); [Thompson et al. 2004](#)). There are limited data to support the use of these agents in mild neurocognitive disorder ([Cooper et al. 2013](#)). The major side effects of AChEIs are gastrointestinal.

## Recommendations

Tacrine is no longer recommended for routine clinical use. Donepezil, rivastigmine, and galantamine are recommended with or without other cognitive enhancers (e.g., memantine). Tolerability is improved by slow dosage

titration. All cholinesterase inhibitors have significant potential for side effects; it is difficult to determine whether one AChEI has a significantly better side-effect profile than another AChEI, given individual patients' variability. Switching AChEIs can be a reasonable treatment strategy if lack of efficacy or tolerability is an issue.

## Donepezil

Donepezil, a piperidine-based, reversible, noncompetitive AChEI with a plasma half-life of about 70 hours, was approved for the treatment of mild to moderate Alzheimer's disease in the United States in 1996 and for severe Alzheimer's disease in 2006. Donepezil is given once daily in 5-mg, 10-mg, or 23-mg doses; 5-mg therapy is only slightly less effective than 10-mg therapy and is an appropriate regimen for mild to moderate Alzheimer's disease, especially when tolerability is an issue ([Birks and Harvey 2006](#)). For moderate to severe Alzheimer's disease, 10-mg or 23-mg therapy is indicated; the 23-mg dose is generally initiated after a patient has been stable for at least 3 months on the 10-mg dose. Donepezil is also available as an orally disintegrating tablet in 5-mg and 10-mg doses. A formulation combining memantine extended-release and donepezil is now available.

Donepezil has shown benefit in treating mild, moderate, and severe Alzheimer's disease ([Birks and Harvey 2006](#); [Wallin et al. 2007](#)) and has been studied for efficacy in patients with mild neurocognitive disorder ([Chen et al. 2006](#); [Pa et al. 2013](#); [Seltzer 2007](#)). A meta-analysis of pooled data on the use of donepezil indicated that caution is warranted in its use to treat mild neurocognitive disorder due to modest treatment effects with significant side effects ([Birks and Flicker 2006](#)). In another review of 41 studies,

donepezil and other AChEIs were not recommended for use in mild neurocognitive disorder ([Cooper et al. 2013](#)).

## Rivastigmine

Rivastigmine, a carbamyl derivative, is a slowly reversible AChEI and BChE inhibitor (BChEI) with an elimination half-life of about 2 hours. It was approved in 2000 for use in the United States and is indicated for the treatment of mild to moderate dementia of Alzheimer's disease and Parkinson's disease. Rivastigmine inhibits the G1 isoenzyme of AChE selectively up to four times more potently than it does the G4 isoenzyme ([Enz et al. 1993](#)). This unique compound with its BChEI properties has been postulated to be of greater benefit than other AChEIs in the treatment of Alzheimer's disease because BChE activity increases in the hippocampus and cortex while AChE activity diminishes ([Tasker et al. 2005](#)); to date, this has not been conclusively shown to be of clinical significance ([Noetzli and Eap 2013](#)). However, as a therapy involving multiple target receptor sites, this agent does have a theoretical advantage over single-target approaches. A recent Cochrane review noted that rivastigmine appears to be beneficial for the treatment of mild to moderate Alzheimer's disease ([Birks and Grimley Evans 2015](#)). Rivastigmine capsules are available in 1.5-mg, 3-mg, 4.5-mg, and 6-mg doses. A rivastigmine skin patch received U.S. Food and Drug Administration approval in 2007; gastrointestinal side effects are reduced in frequency with this drug delivery system. An oral solution is also available.

For Alzheimer's disease, rivastigmine is initiated at 1.5 mg taken orally twice daily. If tolerated, the dosage is increased every 2 weeks, first to 3 mg twice daily and then to 4.5 mg twice daily, up to a maximum dosage of 6 mg

twice daily. Transdermal therapy is initiated at one 4.6-mg skin patch applied daily for at least 4 weeks, at which time the dosage may be increased to the 9.5-mg daily patch. For Parkinson's disease, the oral rivastigmine dosage is increased as done in Alzheimer's disease, except that the minimum interval is extended to every 4 weeks (rather than every 2 weeks), up to a maximum dosage of 6 mg twice daily.

## **Galantamine**

Galantamine hydrobromide, a tertiary alkaloid, is a specific, competitive, and reversible AChEI with a plasma half-life of 6–8 hours that was first marketed in the United States in 2001 as a treatment for mild to moderate dementia of Alzheimer's disease. Galantamine is unique in that it modulates neuronal nicotinic receptors ([Coyle and Kershaw 2001](#)). Whether this nicotinic receptor modulation imparts any significant clinical benefit in disease modification remains unknown. Oral dosing is initiated at 4 mg twice daily, with an increase after a minimum of 4 weeks to 8 mg twice daily as tolerated. The optimal dosage range is 16–24 mg/day. The extended-release galantamine formulation for once-daily dosing has efficacy and side effects similar to those of the twice-daily dosing formulation; it is generally initiated at a dosage of 8 mg/day (taken in the morning), increased to 16 mg/day after a minimum interval of 4 weeks, and (if tolerated after a minimum of 4 additional weeks) increased to 24 mg/day. An oral suspension is available as well. Pooled data from early trials in patients with mild cognitive impairment showed significantly higher rates of death due to bronchial carcinoma, cerebrovascular disorder/syncope, myocardial infarction, and suicide in the galantamine treatment groups ([Cusi et al. 2007](#); [Loy and](#)

[Schneider 2006](#)), although the use of cholinesterase inhibitors, including galantamine, was found to reduce the risk of myocardial infarction and death in a different study ([Nordström et al. 2013](#)). One double-blind, placebo-controlled trial of galantamine with antipsychotic medication in the treatment of subjects with schizophrenia did not show significant benefit, although there was a trend toward improvement in several cognitive domains ([Lee et al. 2007](#)). Galantamine combined with memantine is being actively studied for its potential to improve cognition in schizophrenia ([Koola 2016](#); [Koola et al. 2014](#)).

## Other Agents

Physostigmine, a reversible inhibitor of BChE and AChE, is poorly tolerated due to multiple gastrointestinal side effects, especially nausea and vomiting, and has a very short half-life.

Huperzine alpha (more commonly known as huperzine A) is sold in the United States as a dietary supplement for cognitive enhancement and is a slow, reversible inhibitor of AChE. Huperzine A is believed to have neuroprotective effects by reducing neuronal cell death caused by glutamate ([Ved et al. 1997](#)). The combination of other AChEIs with huperzine A may exacerbate gastrointestinal side effects; patients' usage of this over-the-counter supplement should be monitored, especially if other AChEIs are considered for treatment. ZT-1, a novel huperzine A analogue, is being investigated as an alternative to huperzine A ([Jia et al. 2013](#)).

Metrifonate, a long-acting irreversible cholinesterase inhibitor, was tested in clinical trials, but further development was discontinued after a higher-than-expected

incidence of neuromuscular dysfunction and respiratory paralysis was found.

Selective and nonselective neuronal nicotinic receptor agonists have shown statistically significant cognitive enhancement in young, healthy subjects and mixed results in subjects with Alzheimer's disease ([Dunbar et al. 2007](#); [Frölich et al. 2011](#); [Lombardo and Maskos 2015](#); [Newhouse et al. 1997](#); [Potter et al. 1999](#); [Sunderland et al. 1988](#)). More recent studies have found potential neuroprotective effects from analogues of nicotine and cotinine, a nicotine metabolite with fewer side effects than nicotine ([Gao et al. 2014](#)).

---

## **N-Methyl-D-Aspartate-Related Therapies**

---

Glutamate is an agonist of kainate, NMDA, and  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. Neuronal plasticity of memory and learning is influenced by glutamate's direct modulation of the NMDA postsynaptic receptor; glutamate acts as an excitatory neurotransmitter activating the NMDA receptor. Glutamate excess results in neurotoxicity, affecting cognitive functioning ([Koch et al. 2005](#)).

## **Recommendations**

Memantine appears to reduce the level of cognitive impairment in patients with moderate to severe Alzheimer's disease. Memantine in combination with an AChEI is an

appropriate consideration for improvement in cognition and behavior.

## **Memantine**

Memantine is a noncompetitive NMDA receptor antagonist approved in the United States for treating moderate to severe Alzheimer's disease. The NMDA receptor modulates memory function. Memantine's low-affinity antagonism of glutamate (which has been linked to neurodegeneration and excitotoxicity) may protect against neurotoxicity ([Lipton and Rosenberg 1994](#)). Memantine has been shown to be effective in reducing the level of cognitive impairment in patients with moderate to severe Alzheimer's disease ([Bullock 2006](#); [Nakamura et al. 2014](#); [Reisberg et al. 2003](#)).

Memantine is available in tablets, in extended-release capsules, and as an oral solution; dosing should be adjusted for patients with moderate or severe renal impairment (target of 14 mg/day). It is recommended that memantine tablets be initiated at a dosage of 5 mg/day for 1 week, and increased weekly by 5 mg/day up to a target dosage of 20 mg/day. Memantine tablets are generally given in twice-daily doses, although the elimination half-life ranges from 60 to 80 hours. Memantine is available as an extended-release capsule (7 mg, 14 mg, 21 mg, and 28 mg); it is recommended that memantine capsules be initiated at a dosage of 7 mg/day for 1 week, increasing by 7 mg after a minimum of 1 week to 14 mg/day up to a target dosage of 28 mg/day. Memantine extended-release capsules are given in once-daily dosing. Memantine capsules may be opened and the contents sprinkled on applesauce.

## **Memantine Combination Therapy**

Memantine in combination with an AChEI has been shown to improve cognitive domains significantly and to ameliorate symptoms of behavioral dyscontrol (agitation/aggression, eating/appetite, irritability/lability) ([Cummings et al. 2006](#); [Schmidt et al. 2015](#); [Tariot et al. 2004](#)). Given the disruption of multiple neurotransmitter systems and pathways in Alzheimer's disease and other cognitive disorders, the use of adjunctive cognition-enhancing medications is understandable ([Grossberg et al. 2006](#); [Koola et al. 2014](#)). The specific neurobiological deficits that may be affected by a pharmacological or nutraceutical intervention should be considered. In 2014, fixed-dose combinations of extended-release memantine (14 mg or 28 mg) and donepezil (10 mg) became available. Patients without severe renal impairment who are currently taking donepezil 10 mg once daily and memantine 10 mg twice daily or 28 mg extended-release once daily may be started on the memantine 28 mg/donepezil 10 mg combination tablet (taken once daily in the evening).

---

## **Vascular and Inflammation-Related Therapies**

---

Major known modifiable risk factors for vascular cognitive impairment (with or without dementia) include diabetes mellitus, hypertension, cardiac ischemia, atrial fibrillation, smoking, hyperlipidemia, and peripheral vascular disease ([Desmond et al. 1993](#); [Rockwood et al. 1997](#)). Controversial risk factors include hyperhomocysteinemia. Established vascular therapeutic interventions have included low-dose aspirin and other antiplatelet agents, anti-coagulation

agents, antihypertensives, aggressive management of diabetes mellitus, carotid endarterectomy for selected patients, and treatment of hyperlipidemia. There is a significant overlap of patients with vascular cognitive impairment and those with Alzheimer's disease ([Gearing et al. 1995](#); [O'Brien 1994](#)). Cholinergic receptors (muscarinic and nicotinic) are known modulators of cerebral blood flow ([Schwarz et al. 1999](#); [Zhang et al. 1998](#)). Ischemia-induced NMDA stimulation may cause further cognitive impairment.

A meta-analysis of four randomized, placebo-controlled studies of AChEIs to treat vascular dementia—two with donepezil and two with galantamine—showed statistically significant cognitive enhancement even though the treatment effect was less than what has been observed in Alzheimer's disease patients ([Birks and Flicker 2007](#)). In addition, the authors analyzed pooled results from memantine studies and found statistically significant improvement of cognitive functioning with memantine treatment in patients with vascular impairment similar to that seen with the AChEIs ([Birks and Flicker 2007](#)). A Cochrane review indicated that donepezil in doses of either 5 mg or 10 mg improves both functional ability and cognitive symptoms in patients with mild to moderate vascular cognitive impairment; donepezil was well tolerated in this analysis ([Malouf and Birks 2004](#)). A Cochrane review of the use of galantamine to treat vascular cognitive impairment showed statistically significant results in terms of cognition and executive function with galantamine versus placebo in one study but not in a second study that had fewer subjects; gastrointestinal side effects were noted to be higher in galantamine recipients ([Craig and Birks 2006](#)). Small but clinically detectable treatment effects have been found for donepezil therapy in vascular dementia

([Rockwood et al. 2013](#)). A Cochrane review indicated that rivastigmine had some evidence of benefit in vascular cognitive impairment ([Birks et al. 2013](#)).

## Recommendations

AChEIs appear to have a valid role in the treatment of vascular cognitive impairment. Combination therapy is an important consideration, especially with other known vascular risk modifiers, including aspirin, other nonsteroidal anti-inflammatory drugs (NSAIDs), and cytidine 5'-diphosphocholine (CDP-choline). Randomized controlled trials do not currently support the use of aspirin or other NSAIDs for the treatment of vascular cognitive impairment ([Jaturapatporn et al. 2012](#)). The active use of statins for the prevention and treatment of vascular cognitive impairment is currently not well supported by the literature; however, research with statins remains very active in this pursuit ([McGuinness et al. 2016](#)). Aspirin remains a cornerstone first-line intervention for decreasing potential cardiovascular comorbidity; aspirin may have a future role as a combination therapy with cognitive enhancers.

---

## Other Therapies

---

Antioxidant-related treatment for cognitive impairment remains poorly supported by placebo-controlled, double-blind studies. *Ginkgo biloba* could be classified within several potential treatment categories, including antioxidants, nutraceuticals, cholinergic agents, and

vasodilators; most studies have shown no to only marginal benefit for this agent ([Laws et al. 2012](#)). Vitamin E (including tocopherols and tocotrienols), vitamin C, and carotenoids have antioxidant properties; however, reports of benefit in treating patients with cognitive impairment are mixed. Although antioxidants may have potential as a combination therapy modality, further research is required before endorsing specific treatment recommendations with current antioxidants.

Various other agents have been tested and studied for their potential to improve cognitive impairment; these include secretase inhibitors, tramiprosate, modafinil, hormone replacement therapy, nutraceuticals (*Rubia cordifolia*, *Salvia lavandulaefolia*, *Rosmarinus officinalis*, and *Melissa officinalis*), dehydro-3-epiandrosterone (DHEA), aniracetam, piracetam, latrepirdine, and unifiram. Currently, no recommendations can be made for use of any of these agents as monotherapy or combination therapy.

Antiamyloid immunization may provide one of the greatest opportunities to prevent amyloid- $\beta$  deposition. Immunization strategies generally focus on active or passive immunization and direct central nervous system delivery of anti-amyloid- $\beta$  antibodies. Active immunization with  $\beta$ -amyloid antibodies can reduce plaque formation ([Lemere et al. 2006](#); [Singh et al. 2012](#); [Solomon 2006](#)). Passive immunization with monoclonal antibodies, preparations of immunoconjugates, or entire Alzheimer's disease-associated immunogenes shows promise for treating cognitive impairment due to Alzheimer's disease and may be safer than active immunization ([Geylis and Steinitz 2006](#); [Marciani 2015](#); [Solomon 2007](#)). Active and passive immunization may cause microhemorrhages, and further research continues to seek safer vaccines.

---

# Conclusion

---

The molecular pathogenesis of nerve cell death remains elusive, especially as it relates to the onset and progression of cognitive impairment. Alzheimer's disease and other types of cognitive impairment represent a wide spectrum of neurosystem dysfunction, and no single treatment modality yet found is sufficient to address the global apoptosis and degeneration that occur. Due to the multiple types of neurochemical and substructure dysfunction occurring in cognitive impairment, multiple-drug interventions will likely be required ([Campos et al. 2016](#); [Siskou et al. 2007](#); [Sunderland et al. 1992](#)).

Future studies will explore second-messenger modulation, inhibition of the synthesis of amyloid- $\beta$  using a mimic of the prion protein to inhibit  $\beta$ -secretase cleavage of the amyloid precursor protein, amyloid plaque sheet breakers, AMPA receptor modulators, hyperactive signaling pathway blockers, epigenetic drug candidates, and the role of  $\sigma_1$ -receptor agonists and selective neuronal nicotinic receptor agonists ([Crews and Masliah 2010](#); [Parkin et al. 2007](#); [Rose et al. 2005](#); [Sarter 2006](#)). Currently, the AChEIs and memantine are appropriate choices for slowing the progression of cognitive impairment. Several other promising agents are likely to become available within the next decade.

# CHAPTER 43

## Sedative-Hypnotics

Seiji Nishino, M.D., Ph.D.

Noriaki Sakai, D.V.M., Ph.D.

Kazuo Mishima, M.D., Ph.D.

Emmanuel Mignot, M.D., Ph.D.

William C. Dement, M.D., Ph.D.

In this chapter, we examine some of the pharmacological properties of benzodiazepines, barbiturates, and other sedative-hypnotic compounds, including orexin (hypocretin) receptor antagonists and melatonin receptor agonists (Figure 43-1). *Sedative* drugs moderate excitement, decrease activity, and induce calmness, whereas *hypnotic* drugs produce drowsiness and facilitate the onset and maintenance of a state that resembles normal sleep in its electroencephalographic characteristics. Although these agents are central nervous system (CNS) depressants, they usually produce therapeutic effects at dosages much lower than those that cause coma and generalized depression of the CNS.

**FIGURE 43-1.** History of sedative-hypnotic development.

Some sedative-hypnotic drugs retain other therapeutic uses as muscle relaxants (especially benzodiazepines), antiepileptics, or preanesthetic medications. Although benzodiazepines are used widely as antianxiety drugs, it is not known whether their effect on anxiety is truly distinct from their effect on sleepiness.

Sedative-hypnotics are also important drugs for neuroscientists. These substances modulate basic behaviors such as arousal and response to stress. As our understanding of the molecular structure of the  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) receptor has increased, the mechanisms of these drugs' cellular activity have become clearer. In 2000, it was learned that human narcolepsy with cataplexy was associated with deficiency of orexin (or hypocretin), a newly discovered neuropeptide (Nishino et al. 2000). Although replacement therapies for orexin-deficient narcolepsy using synthetic, small-molecule orexin receptor agonists are not yet available, a dual orexin receptor antagonist

has been developed and was approved for the treatment of insomnia in 2014.

Further understanding of the sedative-hypnotics' modes of action could thus help to elucidate the neurochemical and neurophysiological processes that control sleep and sleep-related physiology and behaviors.

---

## **Benzodiazepines and Benzodiazepine-Like Agents**

---

### **History and Discovery**

Benzodiazepines were first synthesized in the 1930s. The introduction of chlorpromazine and meprobamate in the early 1950s led to a decade of development of sophisticated in vivo pharmacological screening methods that were used to identify the sedative properties of benzodiazepines. More than 3,000 benzodiazepines have been synthesized since chlordiazepoxide (synthesized by Sternbach in 1957; see [Baenninger 2004](#)) was introduced into clinical medicine. About 40 of them are in clinical use.

Several drugs chemically unrelated to the benzodiazepines have been shown to exhibit sedative-hypnotic effects with a benzodiazepine-like profile, and these drugs have been found to act via the benzodiazepine binding site on the GABA<sub>A</sub> receptor (see “Molecular Mechanism of GABA<sub>A</sub>-Benzodiazepine Receptor Interaction” section later in this chapter).

Most of the benzodiazepines currently on the market were selected for their high anxiolytic potential rather than their CNS depressive effects. Nevertheless, all benzodiazepines have sedative-hypnotic properties to various degrees, and some compounds that facilitate sleep have been used as hypnotics.

Mainly because of their remarkably low capacity to produce fatal CNS depression, benzodiazepines have displaced barbiturates as the preferred sedative-hypnotic agents.

## Structure-Activity Relations

The term *benzodiazepine* refers to the portion of the structure composed of benzene rings (A in top portion of [Figure 43-2](#)) fused to a seven-membered diazepine ring (B). However, most of the older benzodiazepines contain a 5-aryl substituent (C) and a 1,4-diazepine ring, and the term has come to mean the 1,4-benzodiazepines.

**Flurazepam**

**Flunitrazepam**

**Diazepam**

**Temazepam**

**Triazolam**

**Clonazepam**

---

**FIGURE 43-2.** Chemical structures of some commonly used benzodiazepines.

A substituent (most often chloride) at position 7 is essential for biological activity. A carbonyl at position 2 enhances activity and is generally present. Most of the newest products also substitute the 2 position, as with flurazepam. These general features are important for the metabolic fate of the compounds. Because the 7 and 2 positions of the molecule are resistant to all major degradative pathways, many of the metabolites retain substantial pharmacological activity.

## Pharmacological Profile

Benzodiazepines share anticonvulsant and sedative-hypnotic effects with the barbiturates. In addition, they have a remarkable ability to reduce anxiety and aggression ([Cook and Sepinwall 1975](#)). In the mammalian CNS, two subtypes of benzodiazepine omega ( $\omega$ ) receptors have been pharmacologically recognized. Benzodiazepine  $\omega_1$  receptors are sensitive to  $\beta$ -carboline, imidazopyridines (e.g., zolpidem), and triazolopyridazines. Benzodiazepine  $\omega_2$  receptors have low affinity for these ligands but relatively high affinity for benzodiazepines. Benzodiazepine  $\omega_1$  sites are enriched in the cerebellum, whereas  $\omega_2$  sites are mostly present in the spinal cord, and both receptor subtypes are found in the cerebral cortex and hippocampus. Benzodiazepine  $\omega_1$  and  $\omega_2$  receptor subtypes are also located peripherally in adrenal chromaffin cells.

Another benzodiazepine subtype,  $\omega_3$ , was identified and is commonly labeled as the *peripheral benzodiazepine receptor subtype* because of its distribution on glial cell membranes in non-nervous tissues such as adrenal, testis, liver, heart, and kidney. This subtype was later detected in the CNS, especially on the mitochondrial membrane, and not in association with GABA<sub>A</sub> receptors ([Gavish et al. 1992](#)). The  $\omega_3$  receptor subtype has high

affinity for benzodiazepines and isoquinoline carboxamides ([Awad and Gavish 1987](#)). The functional role of this receptor subtype is unknown, but it may be involved in the biosynthesis and mediation of the sedative-hypnotic effects of certain neuroactive steroids (e.g., pregnenolone, dehydroepiandrosterone [DHEA], allopregnanolone, tetrahydro-deoxycorticosterone) ([Edgar et al. 1997](#); [Friess et al. 1996](#); [Rupprecht et al. 1996](#)). Neurosteroids modulate GABA<sub>A</sub>-mediated transmission through an allosteric mechanism that is distinct from the modulation mechanism of benzodiazepines and barbiturates. By stimulation of  $\omega_3$  receptors with agonists, cholesterol is transferred from intracellular stores in mitochondria and becomes available to the mitochondrial cytochrome P450 cholesterol side-chain cleavage enzyme (P450scc), and neurosteroid biosynthesis begins ([Papadopoulos et al. 2001](#)). Benzodiazepine  $\omega_3$  receptor subtypes also may serve as mitochondrial membrane stabilizers and protect against pathologically induced mitochondrial and cell toxicity ([Papadopoulos et al. 2001](#)).

The GABA<sub>A</sub> receptor is a ligand-gated ion channel that mediates fast synaptic neurotransmission in the CNS. When the GABA<sub>A</sub> receptor is occupied by GABA or GABA agonists such as muscimol, the chloride channels open and chloride ions diffuse into the cell. Early research established that diazepam (and related benzodiazepines) does not act directly through GABA but instead modulates inhibitory transmission through the GABA<sub>A</sub> receptor in some other way. It was subsequently discovered that benzodiazepines bind specifically to neural elements in the mammalian brain with high affinity and that an excellent correlation exists between drug affinities for these specific binding sites and in vivo pharmacological potencies ([Möhler and Okada 1977](#); [Squires and Brastrup 1977](#)).

The binding of a benzodiazepine to the GABA<sub>A</sub> receptor site is enhanced in the presence of GABA or a GABA agonist, suggesting that a functional (but independent) relationship exists between the GABA<sub>A</sub> receptor and the benzodiazepine receptor binding

sites ([Tallman et al. 1978](#)). Barbiturates (and to some extent alcohol) also seem to produce anxiolytic and sedative effects at least partly by facilitating GABAergic transmission (see “Barbiturates” section later in this chapter). This common action for chemically unrelated compounds can be explained by the shared ability of these compounds to stimulate specific sites on the GABA<sub>A</sub> receptor.

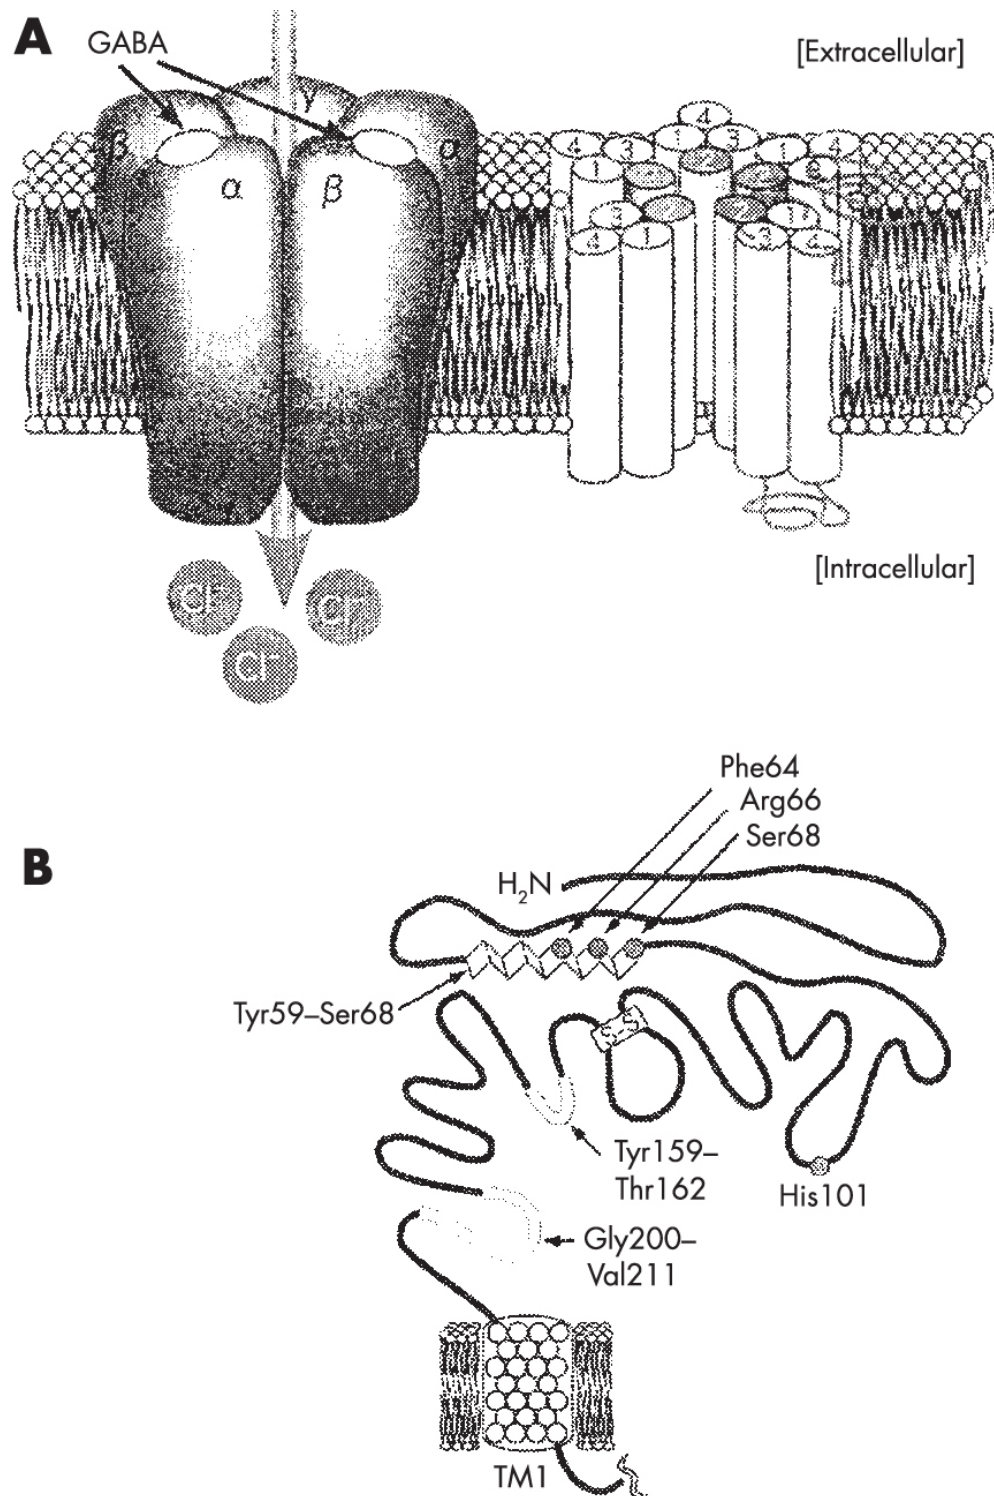

The benzodiazepines bind with high affinity to their binding sites so that the action of GABA at its receptor site is allosterically enhanced. GABA can produce stronger postsynaptic inhibition in the presence of a benzodiazepine. Benzodiazepine agonists are assumed to potentiate only ongoing physiologically initiated actions of GABA (at GABA<sub>A</sub> receptors), whereas barbiturates are thought to cause inhibition at all GABA-ergic synapses regardless of their physiological activity. In addition, barbiturates appear to increase the duration of the open state of the chloride channel, whereas benzodiazepines increase the frequency of channel openings but have little effect on duration ([Twyman et al. 1989](#)). These fundamental differences between the allosteric effects of benzodiazepines within the GABA<sub>A</sub> receptor and the conductive effects of barbiturates on the chloride ion channel may explain why low doses of barbiturates have a pharmacological profile similar to that of benzodiazepines, whereas high doses of barbiturates cause a profound and sometimes fatal suppression of brain synaptic transmission. It is notable that selective GABA<sub>A</sub> receptor agonists, such as muscimol, have no sedative or anxiolytic properties; thus, the entire GABA<sub>A</sub>-benzodiazepine receptor complex must be involved for expression of sedative-hypnotic properties.

## **Molecular Mechanism of GABA<sub>A</sub>-Benzodiazepine Receptor Interaction**

The structure of the GABA<sub>A</sub>-benzodiazepine receptor complex ([Figure 43-3](#)) was elucidated through the cloning of all of the implicated subunit genes and the study of the corresponding

encoded proteins. The GABA<sub>A</sub> receptor is a pentameric protein consisting of five subunits that form a rosette surrounding a transmembrane ion channel pore for Cl<sup>-</sup> (see [Figure 43-3A](#)). The GABA<sub>A</sub> receptor in humans includes the following known subunits:  $\alpha_1$ -  $\alpha_6$ ,  $\beta_1$ -  $\beta_4$ ,  $\gamma_1$ -  $\gamma_4$ ,  $\delta$ ,  $\epsilon$ ,  $\pi$ , and  $\tau$  (seven kinds of subunits, 18 isoforms total) ([Mehta and Ticku 1999](#)). Two alternatively spliced versions of the  $\gamma_2$  subunit,  $\gamma_{2S}$  and  $\gamma_{2L}$ , are also known to exist ([Kofuji et al. 1991](#)).

**FIGURE 43-3.** GABA<sub>A</sub>-benzodiazepine receptor complex.

**(A)** Schematic model of the mammalian  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) receptor embedded in the cell membrane, containing the  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits (in a ratio of 2:2:1). The binding of two molecules of GABA (*arrows*) to the action site (composed of  $\alpha$  and  $\beta$  subunits) triggers the opening of the chloride channel pore, causing chloride ions (Cl<sup>-</sup>) to diffuse into the cell. Each  $\alpha$  or  $\beta$  subunit is composed of four transmembrane (TM) regions (TM1-TM4). The ion channel central pore is lined by TM2 regions contributed by five subunits, arranged in a rosette formation. **(B)** Structure of the  $\alpha_1$  subunit, with amino acid sequence, indicating amino acid residues implicated in GABA and benzodiazepine binding domains.

*Source.* Modified from [Ueno et al. 2001](#).

Despite many studies, the physiological and neuroanatomical processes mediating benzodiazepine action on the GABA<sub>A</sub> receptor complex remain poorly understood. One reason is that the GABAergic system is the most widespread of all inhibitory neurotransmitter systems and could be involved in many circuits responsive to various effects of benzodiazepine agonists. In addition, the various subtypes of GABA<sub>A</sub> receptor have different ligand affinities and channel functions in response to benzodiazepine agonists. These GABA<sub>A</sub> receptor subtypes are broadly distributed in various brain areas to form a mosaic of receptor subtypes ([Wisden and Stephens 1999](#)), making it difficult to understand the functional mechanisms of interaction of benzodiazepine agonists with the GABA<sub>A</sub>-ergic system from the physiological point of view ([Rudolph et al. 1999](#)). However, site-directed mutagenesis and gene knock-in techniques have identified several important features of the benzodiazepine action sites on GABA<sub>A</sub> receptors and their physiological functions ([Ueno et al. 2001](#)).

It is postulated that the binding of GABA to *N*-terminal extracellular domains of  $\alpha$  and  $\beta$  subunits causes conformational changes within the subunits. Ion channel pores subsequently open, and Cl<sup>-</sup> flows across the neuronal membrane, resulting in neuronal inhibition ([Amin and Weiss 1993](#); [Boileau et al. 1999](#); [Sigel et al. 1992](#); [Smith and Olsen 1994](#)) (see [Figure 43-3A](#)). The

extracellular domains of the  $\alpha$  and  $\gamma$  subunits, which consist of about 220 amino acids in the *N*-terminal region, also have been shown to bind GABA and benzodiazepines. “Pharmacologically classified”  $\omega_1$  and  $\omega_2$  receptors are now thought to correspond to GABA<sub>A</sub> receptors possessing the  $\alpha_1$  and  $\alpha_2$  subunits and the  $\alpha_3$  and  $\alpha_5$  subunits, respectively.

Extracellular benzodiazepine binding sites on these subunits consist of several divided portions (see [Figure 43-3B](#)). His101, Tyr159–Thr162, and Gly200–Val211 on  $\alpha_1$  subunits, as well as Lys41–Trp82 and Arg114–Asp161 on  $\gamma_2$  subunits, are essential to formation of the binding pockets ([Boileau et al. 1998](#)). Most strikingly, His101 is a critical residue for diazepam to exhibit its sedative effect ([Crestani et al. 2001](#); [Löw et al. 2000](#); [McKernan et al. 2000](#); [Rudolph et al. 1999](#)). Knock-in mice with displacement of His101Arg are insensitive to benzodiazepine-induced allosteric modulation of the complex but have preserved physiological regulation by GABA ([Rudolph et al. 1999](#)). These knock-in mice failed to be sedated by diazepam but retained other effects of diazepam, such as anxiolytic-like, myorelaxant, motor-impairing, and ethanol-potentiating effects. This suggests the possibility that the sedative action of the benzodiazepine is mediated through GABA<sub>A</sub> receptors possessing the  $\alpha_1$  subunit. It is also noteworthy that His101Arg knock-in mice responded to diazepam and showed sleep changes similar to those seen in wild-type mice, despite the lack of its sedative response in these animals ([Tobler et al. 2001](#)). Thus, the hypnotic and sedative effects of benzodiazepines may be mediated via different subtypes, with hypnotic effects involving GABA<sub>A</sub> receptors possessing subunits other than  $\alpha_1$  (i.e.,  $\alpha_2$ ,  $\alpha_3$ , or  $\alpha_5$ ) ([Tobler et al. 2001](#)).

## **Nonbenzodiazepine Hypnotics (Acting on the Benzodiazepine Receptor)**

Until about 1980, it was widely accepted that the benzodiazepine structure was a prerequisite for the compound’s anxiolytic profile and for benzodiazepine receptor recognition and binding.

However, more recently, three chemically unrelated drugs—the imidazopyridine zolpidem, the cyclopyrrolone zopiclone (and its S[+]-enantiomer, eszopiclone), and the pyrazolopyrimidine zaleplon—have been shown to be useful sedative-hypnotics with benzodiazepine-like profiles ([Figure 43-4](#)). Other chemical classes of drugs that are structurally dissimilar to the benzodiazepines (e.g., triazolopyridazines) but act through the benzodiazepine receptor also have been developed and have demonstrated anxiolytic activity in humans.

**FIGURE 43-4.** Three nonbenzodiazepine hypnotics—zolpidem (an imidazopyridine), zopiclone (a cyclopyrrolone), and zaleplon (a pyrazolopyrimidine)—shown to be useful sedative-hypnotics with benzodiazepine-like profiles.

Nonbenzodiazepine hypnotics have a pharmacological profile slightly different from that of classic benzodiazepines. For example, zolpidem binds selectively to  $\omega_1$  (the 50% inhibitory concentration [IC<sub>50</sub>] ratio for  $\omega_1/\omega_2$  is nearly 1:10) and has more prominent sedative-hypnotic properties relative to other properties such as anxiolytic activity or muscle relaxation. Zolpidem and zopiclone have short half-lives (3 hours and 6 hours, respectively). These drugs appear not to appreciably affect the rapid eye movement (REM) sleep pattern, whereas the amount of slow-wave sleep (SWS) may be slightly increased (Jovanovic and Dreyfus 1983; Shlarf 1992). Rebound effects (insomnia, anxiety), which are commonly seen following withdrawal of short-acting benzodiazepines, are minimal for zolpidem and zopiclone. These compounds also induce little respiratory depression and have less abuse potential than do the common clinical benzodiazepine hypnotics. However, much longer clinical trials are needed to definitively determine whether the imidazopyridines or cyclopyrrolones have any significant advantages over the short- to medium-half-life benzodiazepines in the treatment of insomnia. Eszopiclone, the active stereoisomer of zopiclone with a longer half-life, was approved by the U.S. Food and Drug Administration (FDA) in 2004 and is claimed to be helpful in sleep maintenance as well as sleep induction. Because eszopiclone induces little tolerance, it is suitable for long-term use.

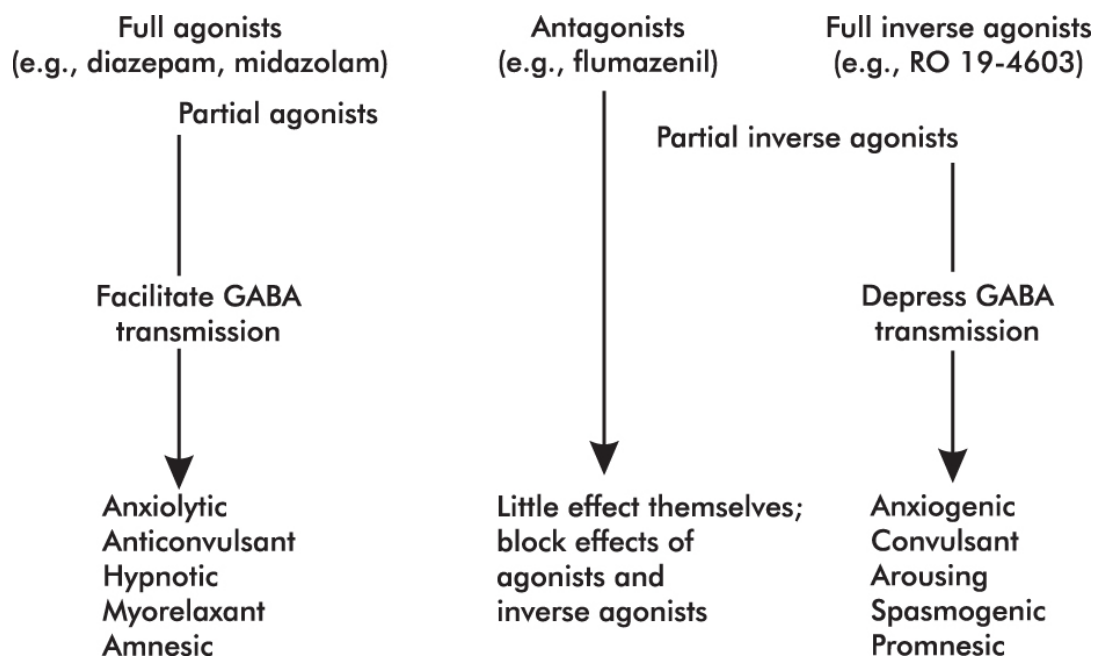

Zaleplon, a pyrazolopyrimidine, also has been developed as a novel nonbenzodiazepine hypnotic (see Figure 43-4). Clinical trials demonstrated that zaleplon is a well-tolerated, safe, rapidly acting, and effective sedative with advantages over lorazepam in regard to unwanted cognitive and psychomotor impairment (Allen et al. 1993; Beer et al. 1994).

## **Benzodiazepine Antagonists, Partial Agonists, and Inverse Agonists**

As knowledge of the relation between the structure of benzodiazepine receptor ligands and their pharmacological properties has increased, potent receptor agonists that stimulate

the receptor and produce pharmacological effects qualitatively similar to those of the classic benzodiazepines have been developed. *Antagonists*, which block the effects of the agonists without having any effects themselves, and *partial agonists*, which have a mixture of agonistic and antagonistic properties, also have been introduced (Haefley 1988). Development of partial agonists may be particularly important in the future because these compounds are free of the ataxic and amnesic side effects commonly associated with the classic benzodiazepine hypnotics.

Braestrup and Nielsen (1986) found that a group of nonbenzodiazepine compounds, the  $\beta$ -carboline, not only antagonized the action of the full agonists but also had intrinsic activity themselves. These compounds are called *benzodiazepine inverse agonists* because they have biological effects exactly opposite those of the pure agonists while also having intrinsic activity like that of agonists. The effects of inverse agonists are blocked by antagonists; thus, the benzodiazepine receptor is unique in that it has a bidirectional function (Figure 43-5).

**FIGURE 43-5.** Properties of the various types of benzodiazepine receptor ligands.

GABA= $\gamma$ -aminobutyric acid.

## Natural Ligands for Benzodiazepine Receptors in the Brain

The presence of benzodiazepine receptors in the brain suggests that natural ligands modulate GABAergic transmission through these sites. Small amounts of endogenous benzodiazepines (e.g., diazepam, desmethyldiazepam) can be detected in human and animal tissues. These benzodiazepines most likely originate from plants, such as wheat, corn, potatoes, or rice, and the levels that are detected are too low to be pharmacologically active (e.g., diazepam,  $<1$  ng/g; desmethyldiazepam, 0.5 ng/g).

Other endogenous benzodiazepine-like substances with neuromodulatory effects probably exist in mammals. Endogenous ligands called *diazepam binding inhibitors*, or *endozepines*, that bind to the benzodiazepine site on the GABA<sub>A</sub>-ergic receptor complex were identified and isolated ([Costa and Guidotti 1991](#); [Marquardt et al. 1986](#); [Rothstein et al. 1992](#)). Like diazepam, these ligands potentiate GABA<sub>A</sub> receptor-mediated neurotransmission by acting as positive allosteric modulators of this receptor. Endozepines are present in the brain at pharmacologically active concentrations and may play a role both physiologically (e.g., regulation of memory, sleep, and learning) and pathologically (e.g., panic attacks, hepatic encephalopathy) ([Mullen et al. 1990](#); [Nutt et al. 1990](#)). Finally, endozepines have been implicated in *idiopathic recurring stupor*, a neurological condition characterized by recurrent episodes of stupor or coma in the absence of any known toxic, metabolic, or structural brain damage ([Cortelli et al. 2005](#)). Endozepine concentrations are greatly increased in the plasma of individuals with this condition, and stupor can be interrupted by injections of flumazenil, a benzodiazepine antagonist. Thus, further knowledge of the roles of endozepines in physiological and pathological processes should be forthcoming once these endogenous ligands have been isolated and characterized ([Farzampour et al. 2015](#); [Rothstein et al. 1992](#)).

[Rye et al. \(2012\)](#) recently reported that the activity of a substance in the cerebrospinal fluid (CSF) that augments inhibitory GABA signaling is enhanced in patients with hypersomnia (including idiopathic hypersomnia with and without long sleep time, long sleepers [ $>10$  hours/day]), and narcolepsy without cataplexy). The authors demonstrated that in the presence of GABA, CSF samples from hypersomnolent patients stimulated GABA<sub>A</sub> receptor function in vitro (measures of GABA<sub>A</sub> receptor-mediated chloride currents in recombinant pentameric human GABA<sub>A</sub> receptor-expressed cultured cells). Interestingly, the stimulation of GABA<sub>A</sub> receptor function induced by the CSF from hypersomnolent patients was significantly greater than that induced by CSF samples from control subjects. The bioactive CSF component had a mass of 500–3,000 daltons and was neutralized by trypsin. The benzodiazepine receptor antagonist flumazenil reversed the enhancement of GABA<sub>A</sub> signaling induced by hypersomnolent CSF in vitro, and flumazenil also normalized vigilance in all seven of the hypersomnolent patients who underwent the drug challenge ([Rye et al. 2012](#)). The authors concluded that a naturally occurring substance in CSF augments inhibitory GABA signaling, revealing a new pathophysiology associated with hypersomnia. These findings also suggest the existence of other endogenous GABA<sub>A</sub> receptor modulators in the CNS.

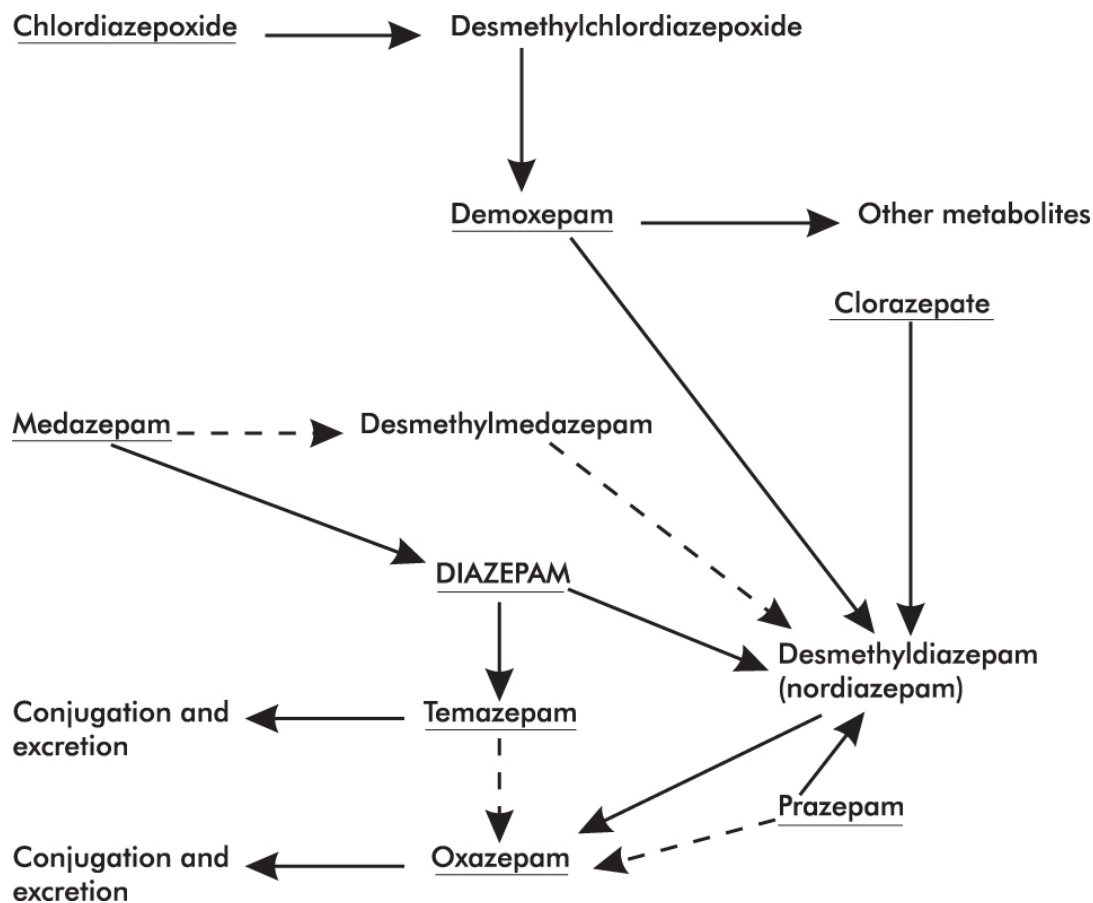

## Pharmacokinetics and Disposition

### **Benzodiazepines**

Benzodiazepines are generally absorbed rapidly and completely. Plasma binding is high (e.g., about 98% for diazepam).

Benzodiazepines are very lipophilic (except for oxazepam), and penetration into the brain is rapid. For swift onset of action, diazepam is available as an emulsion that is administered intravenously for rapid control of epilepsy; midazolam is a water-soluble benzodiazepine suitable for intravenous injection.

The major metabolic pathways for the 1,4-benzodiazepines are shown in [Figure 43-6](#). Medazepam is metabolized to diazepam, which is *N*-desmethylated to desmethyldiazepam. Chlordiazepoxide is also partly converted to desmethyldiazepam. Clorazepate is transformed to desmethyldiazepam. Clorazepate is transformed to desmethyldiazepam.

**FIGURE 43-6.** Metabolic pathways for the principal 1,4-benzodiazepines.

*Solid arrows* and *broken arrows* denote major and minor pathways, respectively; commercially available drugs are underscored. Flurazepam, flunitrazepam, nitrazepam, and triazolam have separate metabolic pathways.

Desmethyldiazepam is a critical metabolite for biological activity because of its long half-life (>72 hours). Because diazepam's half-life is about 36 hours, the concentration of its desmethyl

derivative soon exceeds that of the parent drug during chronic administration. Desmethyldiazepam undergoes oxidation to oxazepam, which (like its 3-hydroxy analog temazepam) is rapidly conjugated with glucuronic acid and excreted.

Among the various benzodiazepines, triazolam has a particularly short half-life (<4 hours), and flurazepam and nitrazepam both have long half-lives. A major active metabolite of flurazepam, *N*-desalkylflurazepam, has a very long half-life (~100 hours).

Because benzodiazepines are often prescribed for long periods, their long-term pharmacokinetics are particularly important. Concentrations of diazepam and desmethyldiazepam reach a plateau after a few weeks. Diazepam concentrations may then decline somewhat without much change in the concentration of the desmethyl metabolite.

Although benzodiazepines can stimulate liver metabolism in some animals, their induction of the hepatic microsomal enzyme system (cytochrome P450 [CYP] enzymes) is of little clinical significance in humans.

## **Nonbenzodiazepine Hypnotics**

Regarding the pharmacokinetics of nonbenzodiazepine hypnotics, no (or only weak) active metabolites exist for the compounds currently available.

## **Effects on Stages of Sleep**

The hypnotic effects of benzodiazepines are thought to derive from the inhibitory effects of the GABAergic system on the raphe and locus coeruleus monoaminergic ascending arousal systems, but this hypothesis may only partially explain their action. Magnocellular regions of the basal forebrain and the preoptic areas have been recognized as important sites for SWS regulation ([Szymusiak 1995](#)). Neurons that are selectively active during SWS have been described in these structures, most typically in the ventrolateral preoptic areas ([Saper et al. 2001](#); [Sherin et al.](#)

1996). These neurons contain GABA and galanin, an inhibitory peptide, and project to the main components of the ascending arousal system, such as the raphe and locus coeruleus and brain-stem cholinergic nuclei (Saper et al. 2001). The ventrolateral preoptic nucleus also sends a dense inhibitory projection to the tuberomammillary histaminergic nucleus, another important wake-promoting system (see Saper et al. 2001; Sherin et al. 1996). Benzodiazepines may thus indirectly modulate these wake-active monoaminergic neurons to promote their hypnotic effects.

Another important site of action for benzodiazepines may be the suprachiasmatic nucleus (SCN). In SCN-lesioned animals, benzodiazepine administration does not induce sleep (Edgar et al. 1993), but the hypnotic effect is restored if the SCN-lesioned animal is sleep deprived before drug administration. Benzodiazepines thus may facilitate the release of a sleep debt accumulated during wakefulness rather than producing de novo sleep (Mignot et al. 1992).

The effects of benzodiazepines on sleep architecture are well known. Most benzodiazepines decrease sleep latency (i.e., the amount of time it takes to fall asleep), especially when first used, and diminish the number of awakenings (Table 43-1). All benzodiazepines increase the time spent in stage 2 sleep. Benzodiazepines also affect the quality of the SWS pattern. Thus, stages 3 and 4 sleep are suppressed and remain so during the period of drug administration. The decrease in stage 4 sleep is accompanied by a reduction in nightmares.

**TABLE 43-1. Comparative effects of benzodiazepines and barbiturates on sleep parameters**

	Benzodiazepines	Barbiturates
Total sleep time	↑ tolerance with short-acting agents	↑ rapid tolerance

*Note.* REM=rapid eye movement sleep; ↑ =increased; ↓ =decreased.

	<b>Benzodiazepines</b>	<b>Barbiturates</b>
Stage 2, %	↑	↑
Slow-wave sleep (stages 3 and 4), %	↓	↓ (slight)
REM latency	↑	↑
REM, %	↓ (slight)	↓
Withdrawal	Rebound insomnia with short-acting agents Carryover effectiveness with long-acting agents REM rebound (slight)	REM rebound Rebound decrease in stage 2 and total sleep time

*Note.* REM=rapid eye movement sleep; ↑ =increased; ↓ =decreased.

Most benzodiazepines increase REM latency. The time spent in REM sleep is usually shortened; however, the reduction in percentage of REM sleep is minimal because the number of cycles of REM sleep usually increases late in the sleep time. Despite the shortening of SWS and REM sleep, the net effect of administration of benzodiazepines is usually an increase in total sleep time, so that the individual feels that the quality of sleep has improved. Furthermore, the hypnotic effect is greatest in subjects with the shortest baseline total sleep time.

If the benzodiazepine is discontinued after 3–4 weeks of nightly use, a considerable rebound in the amount and density of REM sleep and SWS may occur. However, this is not a consistent finding.

Because long-acting benzodiazepine hypnotics impair daytime performance and increase the risk of falls in geriatric patients, several shorter-acting benzodiazepines are the preferred choice for elderly individuals (see section “General Considerations in the Pharmacological Treatment of Insomnia” later in this chapter).

However, it has been found that short-acting benzodiazepines can induce rebound insomnia (a worsening of sleep difficulty beyond baseline levels on discontinuation of a hypnotic) (Kales et al. 1979), rebound anxiety, anterograde amnesia, and even paradoxical rage (Figure 43-7). Many other factors, such as the subtype of insomnia being treated and the dosage and duration of treatment, are also important in explaining the occurrence of these specific side effects, which also may occur with longer-acting benzodiazepines. Nevertheless, enthusiasm for shorter-acting compounds has been tempered by the discovery of these adverse effects.

**FIGURE 43-7.** Duration of action of hypnotics and hangover and rebound insomnia effects.

Hypnotics with long half-lives may impair daytime performance the day after drug administration, whereas short-acting compounds may induce rebound insomnia on discontinuation.

## Indications and Efficacy

Benzodiazepines are the drug treatment of choice in the management of anxiety, insomnia, and stress-related conditions.

Although none of the currently available compounds has any significant advantage over the others, some drugs can be selected to match the patient’s symptom patterns to the pharmacokinetics of the various drugs. If a patient has a persistently high level of anxiety, one of the precursors of desmethyldiazepam, such as diazepam or clorazepate, is most appropriate. Patients with fluctuating anxiety may prefer to take a shorter-acting compound, such as oxazepam or lorazepam, when stressful circumstances occur or are expected.

The indications for nonbenzodiazepine hypnotics are equivalent to those of benzodiazepine hypnotics but may be more specific, depending on the pharmacological property of each compound.

An ideal hypnotic should induce sleep rapidly without producing sedation the next day. Both flurazepam and nitrazepam have inappropriately long half-lives as hypnotics unless a persistent anxiolytic effect is desired the next day (see [Figure 43-7](#)). Even in such situations, diazepam given as a single dose at night may be suitable. Oxazepam penetrates too slowly for a dependable hypnotic effect (slow onset of action). Both lorazepam and temazepam are appropriate treatments for insomnia, but the dosage strengths available are quite high ([Table 43-2](#)). Triazolam is the shortest-acting hypnotic available. When very small doses of benzodiazepines (which are assumed to have no significant hypnotic action) are administered to patients with insomnia, sleep quality often improves greatly, and usually it is not necessary to prescribe a benzodiazepine at a hypnotic dose as a first-choice treatment.

**TABLE 43-2.    Pharmacokinetic properties of GABA-enhancing hypnotic compounds most commonly used in the United States**

Hypnotic compounds	Usual dose (mg)	T <sub>max</sub> (hours) <sup>a</sup>	Half-life (hours) <sup>b</sup>	Active metabolites
--------------------	-----------------	---------------------------------------	--------------------------------	--------------------

Hypnotic compounds	Usual dose (mg)	T <sub>max</sub> (hours) <sup>a</sup>	Half-life (hours) <sup>b</sup>	Active metabolites
<b>Benzodiazepines</b>				
Flurazepam (Dalmane)	15-30	0.5-1.0	48-150	<i>N</i> -Desalkylflurazepam
Quazepam (Doral)	7.5-15	2	48-120	2-Oxoquazepam, <i>N</i> -dealkyl-2-oxoquazepam
Estazolam (ProSom)	1-2	4.9	18-30	1-Oxoestazolam
Temazepam (Restoril)	15-30	1.5	8-20	None
Triazolam (Halcion)	0.125-0.25	1.3	2-6	None
<b>Nonbenzodiazepines</b>				
Zolpidem (Ambien)	5-10	0.8	1.5-2.4	None

*Note.* GABA=γ-aminobutyric acid.

<sup>a</sup>T<sub>max</sub> is the time required to reach maximal (peak) plasma concentration.

<sup>b</sup>Half-life is the time required by the body to metabolize or inactivate half the amount of a substrate taken.

<b>Hypnotic compounds</b>	<b>Usual dose (mg)</b>	<b>T<sub>max</sub> (hours)<sup>a</sup></b>	<b>Half-life (hours)<sup>b</sup></b>	<b>Active metabolites</b>
Zopiclone (Imovane in Canada)	3.75–7.5	1.5	5–6	<i>N</i> -Oxide zopiclone (weak agonist)
Eszopiclone (Lunesta)	1–3	1	6–9	<i>S</i> -Desmethylopiclone (weak agonist)
Zaleplon (Sonata)	5–20	1.0	1.0–2.5	None

*Note.* GABA=γ-aminobutyric acid.

<sup>a</sup>T<sub>max</sub> is the time required to reach maximal (peak) plasma concentration.

<sup>b</sup>Half-life is the time required by the body to metabolize or inactivate half the amount of a substrate taken.

Benzodiazepines can increase the frequency of apneic episodes and exacerbate oxygen desaturation both in healthy subjects and in subjects with chronic bronchitis ([Geddes et al. 1976](#)). Although many reports suggest that benzodiazepines are safe in patients with obstructive sleep apnea, some authors disagree, and it seems wise to avoid hypnotics in patients with severe sleep apnea. One of the only other contraindications is myasthenia gravis, a condition in which muscle relaxation with benzodiazepines can exacerbate muscle atonia.

## Side Effects and Toxicology

When a benzodiazepine is taken at high doses, tiredness, drowsiness, and profound feelings of detachment are common but can be minimized by a careful dose adjustment. Headache, dizziness, ataxia, confusion, and disorientation are less common except in the elderly. A marked potentiation of the depressant

effect of alcohol occurs. Other less common side effects include weight gain, skin rash, menstrual irregularities, impairment of sexual function, and (very rarely) agranulocytosis.

Although otherwise asymptomatic individuals clearly show mental impairment with benzodiazepines, the situation with anxious patients is more complex. Because anxiety itself interferes with mental performance, alleviation of anxiety may result in improved functioning, which more than compensates for the direct drug-related decrement. The effects in some patients may be complicated and unpredictable, even at low dosages.

### **Use During Pregnancy and Lactation**

Because the safety of benzodiazepines in early pregnancy is not established, these compounds should be avoided unless absolutely necessary. Diazepam is secreted in breast milk and may make the infant sleepy, unresponsive, and slow to feed.

### **Overdose**

The benzodiazepines are very widely prescribed, so it is not surprising that they are used in many suicide attempts. For adults, overdoses of benzodiazepines reportedly are not fatal unless alcohol or other psychotropic drugs are taken simultaneously. Typically, the patient falls asleep but is arousable and wakes after 24–48 hours. Treatment is supportive. A stomach pump is usually more punitive than therapeutic, and dialysis is usually ineffective because of high plasma binding.

### **Tolerance and Dependence**

The fact that some patients gradually increase the dose suggests tolerance, but increases in dose are sometimes related to particularly stressful crises.

Dependence, both psychological and physical, occurs with benzodiazepines as with other sedative-hypnotics. Abrupt discontinuation results in withdrawal phenomena such as anxiety, agitation, restlessness, and tension, which are usually delayed for several days because of the long half-life of the major metabolite,

desmethyldiazepam. Even with the normal dose, some patients have withdrawal effects. Psychological dependence is also common, based on the high incidence of repeated prescriptions, but it is mild, and the drug-seeking behavior is much less persistent with benzodiazepines than with barbiturates.

---

## Barbiturates

---

### History and Discovery

Barbital, one of the derivatives of barbituric acid, was introduced in 1903 and soon became extremely popular in clinical medicine because of its sleep-inducing and anxiolytic effects ([Maynert 1965](#)). In 1912, phenobarbital was introduced as a sedative-hypnotic. Since then, more than 2,500 barbiturate analogs have been synthesized, about 50 of which have been made commercially available and only 20 of which remain on the market.

The success of the partial separation of anticonvulsant from sedative-hypnotic properties led to the development of nonsedative anticonvulsants such as phenytoin in the late 1930s and trimethadione in the early 1940s. The success of barbiturates as sedative-hypnotics was largely overshadowed by the discovery of the benzodiazepines in the late 1960s. With pharmacological properties very similar to those of barbiturates, the benzodiazepines have a much safer pharmacological profile. Thus, benzodiazepines have replaced barbiturates in many instances, especially for psychiatric conditions in which suicide is a possibility.

### Structure–Activity Relations

Derivatives of barbituric acid, the parent compound of all barbiturates, do not dissolve readily in water but are quite soluble

in nonpolar solvents. In general, structural changes that increase liposolubility also decrease these compounds' duration of action, decrease the latency to onset of activity, accelerate metabolic degradation, and often increase hypnotic potency.

Compared with barbituric acid derivatives with methyl groups at position 5, those with large aliphatic groups at this position have greater activity but shorter duration of action. However, when aliphatic groups have more than seven carbons, they lose their hypnotic activity and tend to exhibit convulsant activity. Methylation of the 1-*N* atom increases liposolubility and shortens duration of action, and desmethylation may increase the duration of action ([Rall 1990](#)).

## Pharmacological Profile and Mechanism of Action

The main effects of barbiturates are sedation, sleep induction, and anesthesia. Some of the barbiturates, such as phenobarbital, also have selective anticonvulsant properties. The mechanisms of action of barbiturates are complex and still not fully understood. Nonanesthetic doses of barbiturates generally suppress polysynaptic responses. Pertinent to their sedative-hypnotic effects is the fact that the mesencephalic reticular activating system is extremely sensitive to these drugs ([Killam 1962](#)). The synaptic site of inhibition is either postsynaptic (e.g., at the level of cortical and cerebellar pyramidal cells and in the cuneate nucleus, substantia nigra, and thalamus relay neurons) or presynaptic (e.g., in the spinal cord). This inhibition occurs only at synapses where physiological inhibition is GABAergic but not glycinergic or monoaminergic. Thus, barbiturates, like benzodiazepines, specifically potentiate GABA-mediated inhibitory processes in the brain. However, it remains unclear whether all of the effects of barbiturates are entirely mediated by GABAergic mechanisms.

Barbiturates do not displace benzodiazepines from their binding sites; instead, barbiturates enhance benzodiazepine binding by

increasing the affinity of the receptor for benzodiazepines ([Leeb-Lundberg et al. 1980](#)). They also enhance the binding of GABA and its agonists to specific binding sites (Asano and Ogasawara [1981](#)). These enhancement effects are almost completely dependent on the presence of chloride or other anions that are known to permeate the chloride channels associated with the GABA receptor complex, and they are competitively antagonized by picrotoxin (a convulsant) ([Olsen et al. 1978](#)).

The molecular correlations of the barbiturate-acting sites on the GABA<sub>A</sub> receptor also have been studied. However, neither the sequences involved in the binding of GABA and other direct receptor agonists nor the sequence involved in the action of benzodiazepines is of vital importance to barbiturate function ([Amin and Weiss 1993](#)). Whereas some earlier reports suggested that the  $\beta$  subunit alone may form a site for barbiturates ([Sanna et al. 1995](#)), recent studies attempting to identify structural characteristics and binding sites have found that barbiturates bind to the GABA<sub>A</sub> receptor at multiple homologous transmembrane pockets at the subunit interfaces ([Chiara et al. 2013](#)). Although there is still much to be learned, new molecular experimental approaches hold great promise for resolving the most important pharmacological questions regarding which molecular species are important for the anticonvulsant, sedative, anesthetic, and toxic actions of the barbiturates.

## Pharmacokinetics and Disposition

For hypnotic use, barbiturates usually are administered orally. Barbiturates are rapidly absorbed in the stomach, and their absorption decreases when the stomach is full.

Barbiturates are metabolized mainly in the liver. Oxidation of the larger of the two side chains at position 5 is a major catabolic pathway. It generally produces inactive polar metabolites that are rapidly excreted in the urine ([Rall 1990](#)). Changes in liver function can markedly alter the metabolic rate. Chronic administration leads to pharmacokinetic tolerance, even when low or infrequent

doses of barbiturates are used (see subsection “Drug-Drug Interactions” later in this section).

In general, liposolubility decreases both latency to onset of action and duration of action. Thiopental, for example, enters the CNS quickly and is used to rapidly induce anesthesia; barbitone crosses into the brain so slowly that it is inappropriate as a hypnotic drug.

## Effects on Stages of Sleep

Barbiturates decrease sleep latency; however, they also slightly increase fast electroencephalogram (EEG) activity during sleep. Barbiturates decrease body movements during sleep. Stage 2 sleep increases, whereas stage 3 and stage 4 SWS generally decreases (except in some patients who have anxiety and in patients who are addicted to barbiturates; see [Table 43-1](#)). REM sleep latency is prolonged, and both the total time spent in REM sleep and the number of REM cycles are diminished. With repeated nighttime administration of barbiturates, drug tolerance to the effects on sleep occurs in a few days. Discontinuation of barbiturates may lead to insomnia and to disrupted sleep patterns (with a decrease in stage 2 sleep and increases in REM sleep) ([Kay et al. 1976](#)).

## Indications and Efficacy

Although clinical trials have shown that the barbiturates have sedative and hypnotic properties, barbiturates generally compare poorly with benzodiazepines. The patient feels “drugged” the next day, and there is always the risk of fatal overdose because of the depressant effect on respiration. The therapeutic dose of barbiturates may cause fatal respiratory depression in patients with sleep apnea; therefore, barbiturate use is contraindicated in such patients. Because of these risks, many clinicians have stopped using barbiturates as hypnotics and sedatives (one

exception is in the treatment of severe psychomotor excitation) and prescribe them only as anticonvulsants.

Barbiturates also have been administered intravenously to facilitate patient interviews (i.e., amobarbital interview).

Because they enhance porphyrin synthesis, barbiturates are contraindicated in patients with porphyria. Liver function should be checked before and during drug administration. Liver dysfunction can significantly prolong the sedative effects of these drugs and may lead to fatal overdose.

## Side Effects and Toxicology

For many patients who are prescribed barbiturates, it is difficult to control symptoms without causing oversedation. Patients typically oscillate between anxiety and torpor. Mental performance is often impaired, and patients should not drive or operate dangerous machinery.

Patients whose conditions have been stabilized for years with barbiturates must be considered drug dependent. Withdrawal leads to anxiety, agitation, trembling, and, frequently, convulsions. Substitution with a benzodiazepine that can be withdrawn more easily later is often successful.

### Overdose

An overdose of barbiturates leads to fatal respiratory and cardiovascular depression. Suicide attempts frequently involve overdoses of barbiturates, taken either alone or in combination with alcohol or other psychotropic drugs, particularly tricyclic antidepressants. These suicide attempts, unfortunately, are often successful. Depending on local factors such as proximity to a hospital and expertise of staff in intensive emergency care, death occurs in 0.5%–10% of these cases. Severe poisoning results at 10 times the hypnotic dose, and twice that amount may be fatal.

### Tolerance and Dependence

Tolerance to barbiturates occurs rapidly and is a result of both pharmacokinetic factors (e.g., liver enzyme induction) and pharmacodynamic factors (e.g., neuronal adaptation to chronic drug administration). Cross-tolerance develops to alcohol, gas anesthetics, and other sedatives, including benzodiazepines.

Psychological dependence (i.e., drug-seeking behavior) is common. Patients typically visit several physicians to obtain more barbiturates. Physical dependence may be induced by dosages of 500 mg/day. Intoxication may occur, as evidenced by impaired mental functioning, emotional instability, and neurological signs. Abrupt discontinuation after high doses is likely to induce convulsions and delirium. After normal doses, withdrawal phenomena include anxiety, insomnia, restlessness, agitation, tremor, muscle twitching, nausea and vomiting, orthostatic hypotension, and weight loss.

## Drug-Drug Interactions

Barbiturates used with other CNS depressants can cause severe depression. Ethanol is the drug most frequently used in combination with barbiturates, and interactions with antihistaminic compounds are also common. Monoamine oxidase inhibitors and methylphenidate also increase the CNS depressant effect of barbiturates.

Barbiturates may increase the activity of hepatic CYP enzymes two- to threefold. Clinically, this change is particularly important for patients who are also receiving metabolic competitors such as warfarin or digitoxin, for which careful control of plasma concentrations is vital ([Rall 1990](#)).

---

## Other Sedative-Hypnotic Compounds

---

## Alcohol-Type Hypnotics

The alcohol-type hypnotics include the chloral derivatives, of which chloral hydrate (0.5–1.0 g), clomethiazole (192 or 384 mg), and ethchlorvynol (0.5–1.0 g) are still used occasionally in the elderly. Chloral hydrate is metabolized to another active sedative-hypnotic—trichloroethanol. These drugs have short half-lives (~4–6 hours) and decrease sleep latency and number of awakenings; SWS is slightly depressed, but overall REM sleep time is largely unaffected. Chloral hydrate and its metabolite have an unpleasant taste and frequently cause epigastric distress and nausea. Undesirable side effects include light-headedness, ataxia, and nightmares. Chronic use of these drugs can lead to tolerance and occasionally to physical dependence. As with barbiturates, overdose can lead to respiratory and cardiovascular depression, and therapeutic use of these drugs has largely been superseded by the use of benzodiazepines.

## Gamma-Hydroxybutyrate/Sodium Oxybate

$\gamma$ -Hydroxybutyrate (GHB) is a hypnotic agent that has been used mostly in the treatment of insomnia in narcoleptic patients ([Scrima et al. 1990](#)). A small amount of GHB also exists naturally in the CNS ([Bessman and Fishbein 1963](#)). The drug is rarely used in other indications and is frequently abused. GHB was classified as a Schedule I controlled substance in March 2000 in the United States, but in July 2002, the drug's sodium salt form, sodium oxybate (Xynem), was approved for the treatment of narcolepsy. Nighttime administration of GHB (20–40 mg/kg) reduces excessive daytime sleepiness associated with narcolepsy. The compound promotes SWS and REM sleep ([Lapierre et al. 1990](#)), but its effects on sleep architecture are short-lasting, and repeated administration usually is necessary during the night. GHB also is used for the treatment of cataplexy in narcolepsy,

although the mechanisms of GHB's effect on cataplexy remain unknown. The physiological significance of a brain GHB signaling pathway and the detailed mechanisms of many actions of exogenous GHB remain unclear. Exogenously administered GHB induces a wide range of neuropharmacological effects, including sedation, memory impairment, an increase in sleep, seizures, dependence/abuse, and coma ([Wong et al. 2004](#)). GHB has long been known to have an effect on dopamine systems in the brain and likely inhibits dopamine release ([Vayer et al. 1987](#)).

Most of the effects of exogenous GHB have been shown to be mediated (either fully or in part) by GABA<sub>B</sub> receptors ([Castelli et al. 2004](#); [Maitre 1997](#); [Wong et al. 2004](#)). In 2003, the cloning of a putative GHB receptor was reported ([Andriamampandry et al. 2003](#)).

Despite this progress, there is an urgent need for a well-validated functional assay for GHB receptors. Moreover, because GHB can also be metabolized to GABA, it remains to be seen whether the many GABA<sub>B</sub> receptor-mediated actions of GHB are caused by GHB itself acting directly on GABA<sub>B</sub> receptors or by a GHB-derived GABA pool (or both) ([Wong et al. 2004](#)).

## Antihistamines

Antihistamines such as promethazine (25–50 mg), diphenhydramine (25–50 mg), and doxylamine (25 mg) are sometimes prescribed as sleep inducers. They decrease sleep latency but do not increase total sleep time (see [Reite et al. 1997](#)). These compounds are especially useful for patients who cannot sleep well because of acute allergic reactions or itching. Because sedative antihistamines lack abuse potential, they also may be a good choice for individuals with substance use disorders. However, rapid tolerance is a problem.

In April 2008, doxepin hydrochloride (marketed under the trade name Silenor), a tricyclic antidepressant with histamine 1 (H<sub>1</sub>) receptor antagonism, received FDA approval for the treatment of

insomnia. Doxepin (as Sinequan) (3 and 6 mg) reduces wake after sleep onset and prolongs total sleep time ([Markov and Doghramji 2010](#)). Several other selective H<sub>1</sub> receptor blockers and H<sub>1</sub> receptor reverse agonists are also under development for use as hypnotics.

## Melatonin and Melatonin Receptor Agonists

### Melatonin

Melatonin is a neurohormone produced by the pineal gland during the dark phase of the day-night cycle. In animals, melatonin has been implicated in the circadian regulation of sleep and in the seasonal control of reproduction. Studies suggest that melatonin administration may have some therapeutic effects in various disturbances of circadian rhythmicity, such as those related to jet lag ([Arendt et al. 1987](#)), shift work ([Folkard et al. 1993](#)), non-24-hour sleep-wake cycle in blind individuals ([Arendt et al. 1988](#)), and delayed-sleep-phase insomnia ([Dahlitz et al. 1991](#)), with few side effects (e.g., headaches or nausea). High doses of melatonin (3–100 mg), which increase serum melatonin levels far beyond the normal nocturnal range, have been suggested to produce hypnotic effects in humans ([Dollins et al. 1994](#)). Lower and more physiological doses of melatonin (e.g., 0.3 mg) might also be active ([Zhdanova et al. 2001](#)).

In humans, the production of melatonin during the dark period declines with age; this effect parallels declines in sleep quantity and quality ([van Coevorden et al. 1991](#)), especially in elderly persons with insomnia ([Haimov et al. 1994](#); [Mishima et al. 2001](#)). These findings appear to suggest that deficiencies in nocturnal melatonin secretion might contribute to disrupted sleep in the elderly; thus, melatonin may be particularly beneficial for insomnia in this population. Indeed, some studies reported favorable effects with supplementary administration of melatonin

in elderly persons with disturbances in sleep maintenance ([Garfinkel et al. 1995](#); [Haimov et al. 1995](#)). However, several studies reported contradictory findings indicating no significant relation between physiological melatonin secretion levels and sleep-maintenance parameters ([Hughes et al. 1998](#); [Lushington et al. 1998](#); [Youngstedt et al. 1998](#); [Zeitzer et al. 1999](#)), as well as no significant therapeutic effect of melatonin replacement on sleep maintenance in elderly persons with insomnia ([Hughes et al. 1998](#)).

One of the difficulties in establishing the therapeutic efficacy of melatonin is its short half-life (20–30 minutes). Bedtime melatonin administration (1–3 mg) reduces sleep latency but has few objective effects on sleep architecture. It is also unclear whether the hypnotic effect from a physiological or pharmacological dose represents a direct effect on sleep, an indirect effect on circadian timing that subsequently gates the release of sleep, or both. Finally, very few double-blind, placebo-controlled studies have been done, and most current reports are confounded by strong placebo effects in the context of a melatonin fad. Melatonin might be an effective hypnotic in some indications, but better-controlled studies are needed to establish its efficacy in specific indications. The purity of the products sold in health food stores is also a problem, and the long-term effects of melatonin administration in humans are unknown.

A prolonged-release formulation of melatonin (marketed under the trade name Circadin) was approved by the European Commission in June 2007 as monotherapy (2 mg) for the short-term treatment of primary insomnia characterized by poor-quality sleep in patients 55 years and older ([Lemoine et al. 2007](#)).

## Melatonin Receptor Agonists

There are at least three subtypes of melatonin receptor with high ( $MT_1$  or  $MT_{1a}$ ) and low ( $MT_2$  or  $MT_{1b}$  and  $MT_3$  or  $MT_{1c}$ ) affinities for this ligand ([Dubocovich 1995](#); [Morgan et al. 1994](#); [Reppert et al. 1994, 1995](#)). The localization of the  $MT_1$  receptor in the SCN, median eminence, and retina in humans and rodents suggests

that this receptor is essential for circadian regulation and reproduction, whereas the MT<sub>2</sub> receptor is localized mainly in the retina. Melatonin receptors in the retina likely play an important role in retinal physiology, including circadian regulation ([Sengupta et al. 2011](#)) and photopigment disc shedding ([Besharse and Dunis 1983](#)).

Ramelteon (8 mg), a melatonin receptor agonist with both high affinity for melatonin MT<sub>1</sub> and MT<sub>2</sub> receptors and low affinity for the MT<sub>3</sub> receptor and with a longer half-life than melatonin, was approved by the FDA in July 2005 for the treatment of insomnia characterized by difficulty with sleep onset (see [Kuriyama et al. 2014](#); [Takeda Pharmaceuticals America, Inc. 2010](#)). Ramelteon does not show any appreciable binding to GABA<sub>A</sub> receptors, which are associated with anxiolytic, myorelaxant, and amnesic effects. Ramelteon has not been demonstrated to produce dependence and has shown no potential for abuse, and the withdrawal and rebound insomnia typically seen with other GABA modulators do not appear to be present.

Animal studies demonstrated that the sleep-enhancing effects of ramelteon are not associated with reductions in REM sleep ([Miyamoto et al. 2004](#)). Ramelteon is currently the only nonscheduled prescription drug for the treatment of insomnia available in the United States. It has no appreciable affinity for receptors that bind neuropeptides, cytokines, serotonin, dopamine, norepinephrine, acetylcholine, and opiates. It also does not interfere with the activity of any known enzymes in standard panels. The activity of ramelteon at the MT<sub>1</sub> and MT<sub>2</sub> receptors, especially those in the SCN, is believed to contribute to its sleep-promoting properties, as these receptors, acted upon by endogenous melatonin, are thought to be involved in maintenance of the circadian rhythm underlying the normal sleep-wake cycle.

The activity of ramelteon is similar to the biological action of melatonin. No published studies have reported comparative data on whether ramelteon is more or less safe or effective than melatonin, a much less expensive drug widely available in the United States without a prescription.

Recent studies have reported findings suggesting that melatonin (0.5 mg) or ramelteon (8 mg) can prevent delirium in elderly patients ([Al-Aama et al. 2011](#); [Hattai et al. 2014](#)). Although significant decline in melatonin levels during aging has been reported by many investigators ([Srinivasan et al. 2006](#)), the mechanisms by which these drugs might reduce or prevent delirium in elderly patients are not known.

Another MT<sub>1</sub>/MT<sub>2</sub> receptor agonist, tasimelteon ([Rajaratnam et al. 2009](#)), was approved by the FDA in January 2014 for the treatment of non-24-hour sleep-wake disorder (N24HSWD) in totally blind people ([Vanda Pharmaceuticals Inc. 2016](#); see also [Sack et al. 1991](#)). Melatonin receptor agonists can produce improvements in sleep timing similar to those produced by melatonin. Synthetic melatonin receptor agonists may also be useful in patients who experience insomnia due to shift work or jet lag, as well as delayed sleep phase syndrome or advanced sleep phase syndrome; beneficial effects of melatonin were reported in these conditions.

## Orexin (Hypocretin) Receptor Antagonists

Orexin A (or hypocretin 1) and orexin B (or hypocretin 2) are newly discovered hypothalamic neuropeptides that play critical roles in the promotion and maintenance of wakefulness and in the pathophysiology of narcolepsy with cataplexy ([Nishino 2011](#); [Sakurai et al. 1998](#)). In humans, chronic loss of orexin neurons is associated with narcolepsy with cataplexy (i.e., *International Classification of Sleep Disorders*, 3rd Edition [ICSD-3; [American Academy of Sleep Medicine 2014](#)]-defined type 1 narcolepsy). Orexin neurons are presumed to be most active during wakefulness and least active during sleep. Two G protein-coupled receptors for orexin peptides (orexin receptor 1 and orexin receptor 2) have been identified ([Nishino 2011](#); [Sakurai et al. 1998](#)).

Although efforts to develop therapies for type 1 narcolepsy using orexin receptor agonists are still in progress, an orally active dual orexin receptor antagonist has been developed, and in August 2014, this agent—suvorexant (marketed under the name Belsomra)—received FDA approval for the treatment of adult patients with insomnia characterized by difficulties with sleep onset and/or sleep maintenance (see [Winrow et al. 2011](#); [Yang 2014](#); also see [Merck & Co 2014](#)). The recommended dosage is 10 mg/day (a maximum of 20 mg once daily), to be taken orally once every night within 30 minutes of bedtime and with at least 7 hours remaining until the planned wake time.

Suvorexant has demonstrated efficacy in both inducing and maintaining sleep ([Jacobson et al. 2014](#)). In Phase II and Phase III studies of suvorexant 15 mg or 20 mg once daily versus placebo, significantly greater improvements on both subjective (total sleep time) and objective (polysomnography-determined wake time after sleep onset) measures were seen at 1 night, 1 month, and 3 months ([Jacobson et al. 2014](#)).

Suvorexant is contraindicated in people diagnosed with narcolepsy, given that the effects of orexin receptor antagonists in narcolepsy—either ICSD-3 type 1 (hypocretin deficient) or type 2 (hypocretin nondeficient)—are not predictable ([Merck & Co 2014](#)). Use of suvorexant is not recommended for individuals with liver impairment or for those who are taking medications that strongly inhibit the CYP3A4 enzyme, such as itraconazole, lopinavir/ritonavir, clarithromycin, ritonavir, ketoconazole, indinavir/ritonavir, or conivaptan ([Merck & Co 2014](#)).

Suvorexant is well tolerated. Adverse effects include next-day sleepiness and fatigue and issues with driving, as well as unusual dreams ([Merck & Co 2014](#)). Sleep paralysis and hypnagogic/hypnopompic hallucinations also have been reported to occur.

Suvorexant's median time to peak plasma concentration ( $T_{\max}$ ) is 2 hours under fasting conditions ([Merck & Co 2014](#)). For a suvorexant 10-mg dose, the mean absolute bioavailability is 82%. Administration of suvorexant with a high-fat meal had no clinically

significant effects on systemic drug exposure but delayed  $T_{\max}$  by 1.5 hours. Steady state is achieved within 3 days. Suvorexant is primarily metabolized by CYP3A4, with a minor contribution from CYP2C19. The main circulating compounds are the unchanged drug and a hydroxyl metabolite, which is not expected to be pharmacologically active. Suvorexant is primarily eliminated in the feces, with about 66% of a radiolabeled dose recovered in the feces (vs. 23% in the urine). The mean elimination half-life of suvorexant is 12 hours.

Concomitant use of suvorexant with other CNS depressant drugs (e.g., benzodiazepines, opioids, tricyclic antidepressants) may produce additive effects; dosage adjustments in either or both drugs may be required ([Merck & Co 2014](#)).

Although it is unlikely that orexin receptor antagonists are themselves addictive, suvorexant has been classified as a Schedule IV controlled substance. There are as yet no published studies comparing suvorexant with other medications used for insomnia. Because insomnia is a very heterogeneous disease condition, it is likely that many patients will benefit from this new agent, and large amounts of clinical data should soon be available.

---

## General Considerations in the Pharmacological Treatment of Insomnia

---

The *International Classification of Sleep Disorders* is the classification system most commonly used by sleep medicine specialists. The first edition of the *International Classification of Sleep Disorders* (ICSD) was published in 1990, and the ICSD was subsequently revised in 2005 (ICSD-2) and 2014 (ICSD-3). The sleep disorder classification in the fifth edition of *The Diagnostic and Statistical Manual of Mental Disorders* (DSM-5; [American](#)

[Psychiatric Association 2013](#)) is similar to that in the ICSD-3 ([American Academy of Sleep Medicine 2014](#)).

Insomnia is a subjective complaint of insufficient, inadequate, or nonrestorative sleep ([Buysse and Reynolds 1990](#)). The ICSD-3 defines insomnia as “a persistent difficulty with sleep initiation, duration, consolidation, or quality that occurs despite adequate opportunity and circumstances for sleep and results in some form of daytime impairment” ([American Academy of Sleep Medicine 2014](#)). Inadequate sleep causes disturbances in daytime functioning, such as fatigue, mood problems, and impaired performance.

Insomnia is a common symptom. Estimates of its prevalence depend on the definition criteria used and the population studied. As a result of these differences in case definition, prevalence estimates have varied widely—from 10% to 40% ([Mai and Buysse 2008](#))—but tend to average about 30% for insomnia and 5%–10% for specific insomnia disorders at ([Roth 2007](#)). The current use of hypnotics in the general population is estimated to range between 3.5% and 11.7% ([Mellinger et al. 1985](#); [Ohayon and Caulet 1996](#); [Ohayon et al. 1998](#); [Quera-Salva et al. 1991](#)).

Insomnia is a symptom that must be explored clinically before treatment is initiated. Sleep disturbances often indicate a larger psychiatric problem, such as depression. As mentioned earlier, insomnia is a common complaint in older populations, especially in institutional settings. In some cases, environmental factors (e.g., noise) or other sleep disorders (e.g., periodic leg movements, sleep apneas, parasomnias) may be involved.

## Insomnia Classifications Based on Duration

A useful initial approach to the patient with insomnia is to consider the duration of the complaint. The duration of the insomnia not only suggests its cause but also provides some guidance on how best to use hypnotics in its treatment.

The ICSD-3 identifies three distinct types of insomnia: short-term insomnia, chronic insomnia, and other insomnia (for insomnia symptoms that do not meet criteria for short-term or chronic insomnia). Previous ICSD editions had subclassified chronic insomnia into primary and comorbid types, but these subclasses were eliminated in the ICSD-3 because it was judged that they did not improve diagnostic accuracy.

## **Chronic insomnia Disorder**

ICSD-3 consolidates all chronic insomnia diagnoses under a single disorder, chronic insomnia disorder. Chronic insomnia disorder requires a report of a sleep initiation or sleep maintenance problem, an adequate opportunity and circumstances to sleep, and daytime consequences as the result of the insomnia symptoms.

To meet diagnostic criteria for chronic insomnia disorder, the patient should have symptoms at least three times per week over a duration of 3 or more months. Because insomnia is a component of many psychiatric and medical conditions, a diagnosis of chronic insomnia disorder should be considered only when the insomnia is very prominent and requires further evaluation and treatment.

Chronic insomnia (several months or even years) should first be evaluated with a sleep log of a 2-week period. Most commonly, some degree of sleep-state misperception is present, and patients with chronic insomnia may greatly exaggerate the complaint. In rare cases, insomnia began in childhood and has persisted into adulthood (idiopathic insomnia). In chronic insomnia, improved sleep hygiene and various behavioral techniques that aim to reduce negative conditioning (e.g., stimulus control therapy, sleep restriction, phototherapy) are often helpful on a long-term basis, but these methods are successful only if the patient is motivated and if specialized clinical supervision is available. Pharmacotherapy is most appropriate for patients whose sleep disturbance is clearly causing some daytime dysfunction. If the clinician decides to prescribe medication, it is always helpful to start with the lowest dose of hypnotic possible to reduce the risk

of tolerance and dependence; in addition, it is recommended that daily use be avoided if possible.

## **Short-Term Insomnia Disorder**

To meet diagnostic criteria for ICSD-3 short-term insomnia disorder, the patient must meet the same criteria required for chronic insomnia disorder except that the symptom duration may be less than 3 months. Development of symptoms is often temporarily related to a significant stressor. To qualify for this diagnosis, the insomnia must be an independent focus for the patient and/or require separate clinical attention. Short-term insomnia disorder often resolves when the stressor does, or when the patient develops adequate coping mechanisms or adapts to the stressor ([American Academy of Sleep Medicine 2014](#)).

Transient insomnias (1-2 days) are common and are typically caused by an environmental acute stressor, jet lag, or shift work; these insomnias usually do not require pharmacological treatment. However, if medication is prescribed for transient symptoms, benzodiazepine hypnotics (or other hypnotics with fewer side effects) may be used, because dependency is unlikely to develop when the therapy lasts less than 7-10 days.

It is particularly important that transient and short-term (a few days to a few months) insomnias be recognized and treated so that they do not evolve into longer-term, enduring disorders, such as psychophysiological insomnia. In this subtype, the patient begins to worry excessively about his or her sleep, so that what may have begun as a brief period of insomnia during a stressful time transitions into a behaviorally learned chronic sleep disorder that does not resolve once the stressful period is over. In psychophysiological insomnia, daily use of benzodiazepine hypnotics is also dangerous because it may lead to tolerance and dependence. The clinician should provide reassurance regarding the favorable resolution of the stressful event, and the patient should be instructed to use hypnotic medications intermittently to avoid developing tolerance. Education in proper sleep hygiene is

also important to reduce the possibility of evolution into a chronic problem.

## Insomnia Classifications Based on Clinical Features

Insomnia also can be classified on the basis of individual clinical features—that is, problems with sleep initiation, sleep maintenance, or termination (early-morning awakening). In this context, the most important pharmacological properties to consider when selecting a hypnotic for treatment are how quickly it acts and how long the effects last (see [Table 43-2](#) for this information for commonly used compounds). The rate of absorption is the most critical factor determining onset of action.  $T_{\max}$  is the pharmacological parameter that best predicts onset of action. After absorption, hypnotics are distributed to various organs; distribution and drug elimination influence the duration of action. The elimination half-life (see [Table 43-2](#)) usually provides a good first estimate of the duration of action for drugs that have comparable absorption and distribution profiles.

Hypnotics with a long duration of action are helpful for patients who have difficulty in both initiating and maintaining sleep. One advantage of these long-acting compounds is that rebound insomnia is often delayed and milder if the drugs have to be withdrawn (see [Figure 43-7](#)). Patients who have difficulty initiating sleep might prefer short-acting compounds; however, for these compounds, it may be necessary, paradoxically, to switch to longer-acting hypnotics before withdrawal of all hypnotic treatment.

The importance of determining whether insomnia is the symptom of an underlying neuropsychiatric condition must be emphasized (see [Chapter 53](#) in this volume, “Treatment of Insomnia,” by Krystal). If depression is a contributing factor, a sedating antidepressant such as amitriptyline, doxepin, or trazodone can be used alone or in combination with a hypnotic

(see [Chapter 46, “Treatment of Depression,”](#) by Bobo and Shelton). Individuals with schizophrenia can experience persistent insomnia (affecting both initiation and maintenance of sleep), and antipsychotics with sleep-enhancing effects, such as olanzapine or quetiapine, may be effective therapies (see [Chapter 49, “Treatment of Schizophrenia,”](#) by Woo et al.). For insomnia associated with anxiety disorders, hypnotics supplemented with anxiolytics can be used (see [Chapter 48, “Treatment of Anxiety and Related Disorders,”](#) by David and Davidson).

## Special Considerations for Insomnia Treatment in Elderly Patients

Sleep disturbances are very frequent complaints in old age, and treatment must be initiated carefully in this population. Between 5% and 33% of elderly people in North America and the United Kingdom are prescribed a benzodiazepine or a benzodiazepine receptor agonist (e.g., zolpidem, zopiclone, zaleplon) for sleep problems ([Aparasu et al. 2003](#); [Craig et al. 2003](#); [Gottlieb 1990](#); [Jaussent et al. 2013](#)), and this segment of the population receives 35%–40% of all sedative-hypnotic prescriptions ([Gottlieb 1990](#)).

Before starting pharmacological therapy, all possible causes of insomnia should be examined (e.g., psychophysiological; associated with drugs or alcohol; due to disturbance of the sleep-wake cycle; associated with periodic leg movements, sleep apnea, or other physical or psychiatric conditions). Likewise, before selecting a specific hypnotic, the clinician should consider its pharmacological properties and side-effect profile, the patient’s medical health and medical history, and the patient’s history of sedative-hypnotic use. The special case of melatonin and melatonin receptor agonists was discussed earlier in this chapter (see section “Other Sedative-Hypnotic Compounds”). Data on the efficacy of orexin receptor antagonists in elderly people are still being accumulated.

Hypnotics or their active metabolites often accumulate during chronic use in elderly patients, and this accumulation may cause cognition problems, disorientation, confusion, and (occasionally) falls. Hypnotics with short or intermediate half-lives are thus recommended, and the lowest dose possible should be used. Compounds with a short half-life, such as triazolam or zolpidem, may be effective for problems with sleep initiation and sleep fragmentation. Zolpidem has little muscle-relaxant effect and may be preferable to triazolam. Compounds with an intermediate hypnotic profile, such as estazolam or temazepam, are also reported to be effective in elderly patients. Hypnotics with an intermediate half-life may alter daytime performance and memory to a lesser extent than regular hypnotics, and they are not as likely to induce rebound insomnia after withdrawal.

---

## Conclusion

---

The mechanism of action of most currently available hypnotics (benzodiazepines, barbiturates, alcohol, and nonbenzodiazepine hypnotics) involves a modulatory effect on GABAergic activity. These compounds stimulate GABAergic transmission by acting on the GABA<sub>A</sub>-benzodiazepine-Cl<sup>-</sup> macromolecular complex, which is known to contain multiple modulatory binding sites and many receptor subtypes. This recently discovered molecular diversity within the macromolecular complex suggests that new GABAergic hypnotic compounds, including newly developed nonbenzodiazepine hypnotics with subtype selectivity, may have more favorable side-effect profiles.

Other non-GABAergic hypnotics, including sedative antidepressants, antihistamines, melatonin and melatonin receptor agonists, and (most recently) orexin receptor antagonists, are useful strategies in the treatment of insomnia, especially because these hypnotics may lack some of the hampering side effects often seen with classical GABAergic hypnotics, such as abuse potential and amnesic effects.

Prescription of these non-GABAergic hypnotics, as with the prescription of other regular benzodiazepine-like hypnotic compounds, should be guided by the knowledge that insomnia is a heterogeneous condition that must be explored clinically before any pharmacological treatment is initiated.

## CHAPTER 44

# Psychostimulants and Wakefulness-Promoting Agents

Charles DeBattista, D.M.H., M.D.

**Amphetamine**, first discovered in 1887, and the subsequently developed stimulants have been used in clinical psychiatry with varying results. Beyond their use for attention-deficit/hyperactivity disorder (ADHD), stimulants have been used for symptomatic relief based on their effects on mood and hedonic drive. Research into the use of stimulants as adjunctive agents in the treatment of specific symptoms and syndromes has been increasing. Various common adjunctive psychotherapeutic uses for stimulants, such as depression, have not been well researched, whereas other indications, such as narcolepsy, are backed by considerable clinical data. In this chapter, I review the pharmacology of these medications and their indications (Tables 44-1 and 44-2).

**TABLE 44-1. FDA classifications of psychostimulants and wakefulness-promoting agents**

Agent	Schedule	Approved for	Medication type	Abuse potential
Amphetamine	II	ADHD, narcolepsy	Anorexiant/stimulant	Black box warning
Lisdexamfetamine	II	ADHD	Stimulant	Black box warning
Methylphenidate	II	ADHD, narcolepsy	Anorexiant/stimulant ("Mild stimulant")	Black box warning

*Note.* ADHD=attention-deficit/hyperactivity disorder; FDA=U.S. Food and Drug Administration; OSAHS=obstructive sleep apnea/hypopnea syndrome; SWSD=shift-work sleep disorder.

*Source.* Adapted from *Physicians' Desk Reference*, 60th Edition. Montvale, NJ, Medical Economics Company, 2006.

<b>Agent</b>	<b>Schedule</b>	<b>Approved for Medication type</b>	<b>Abuse potential</b>
Modafinil	IV	Excessive daytime sleepiness associated with narcolepsy, OSAHS, and SWSD	Wakefulness-promoting agent Reinforcing
Armodafinil	IV	Excessive daytime sleepiness associated with narcolepsy, OSAHS, and SWSD	Wakefulness-promoting agent Reinforcing

*Note.* ADHD=attention-deficit/hyperactivity disorder; FDA=U.S. Food and Drug Administration; OSAHS=obstructive sleep apnea/hypopnea syndrome; SWSD=shift-work sleep disorder.

*Source.* Adapted from *Physicians' Desk Reference*, 60th Edition. Montvale, NJ, Medical Economics Company, 2006.

**TABLE 44-2. Amphetamine and methylphenidate preparations**

<b>Stimulant</b>	<b>Time to effect</b>	<b>Peak (hours)</b>	<b>Duration (hours)</b>	<b>Dosing</b>
<b>Amphetamine preparations</b>				
Adderall <sup>a</sup>	~ 1 hour	3	6-9	bid
Adderall XR	1-2 hours	7	6-10	qd (or bid)
Dexedrine	1 hour	3	4-6	bid or tid
Dexedrine Spansules	1 hour	4	6-10	qd or bid
Desoxyn (methamphetamine)	40 minutes	1-3	4-24	qd, bid, or tid

*Note.* bid = twice daily; qd = once daily; tid = three times daily.

<sup>a</sup>Amphetamine/dextroamphetamine, 1:3 ratio.

<sup>b</sup>Laser hole in capsule allows passage of drug; osmotically active push layer expels drug.

<sup>c</sup>Rapid-release and continuous-release beads give biphasic response.

<b>Stimulant</b>	<b>Time to effect</b>	<b>Peak (hours)</b>	<b>Duration (hours)</b>	<b>Dosing</b>
Vyvanse (lisdexamfetamine)	~ 1 hour	2	9	qd
<b>Methylphenidate preparations</b>				
Methylphenidate	15-30 minutes	1-2	4-5	bid or tid
Focalin (dexamethylphenidate)	15-30 minutes	1-2	4-5	bid or tid
Ritalin SR (tablet)	1-2 hours	5	8	qd or bid
Concerta <sup>b</sup>	1-2 hours	6-8	12	qd or bid
Metadate-CD <sup>c</sup>	1 hour	Biphasic: 1-2 and 4-5	6-8	qd or bid

*Note.* bid = twice daily; qd = once daily; tid = three times daily.

<sup>a</sup>Amphetamine/dextroamphetamine, 1:3 ratio.

<sup>b</sup>Laser hole in capsule allows passage of drug; osmotically active push layer expels drug.

<sup>c</sup>Rapid-release and continuous-release beads give biphasic response.

## Amphetamines

### Structure-Activity Relations

Structurally, amphetamine is phenylisopropylamine. Ultimate pharmacological action is determined by alterations to any of the three basic parts of the amphetamine molecule.

#### Amine Changes

In terms of affecting clinical utility, substitution at the amine group is the most common alteration. Methamphetamine (both L and D isomers), which is characterized by an additional methyl group attached to the amine, making it a secondary substituted amine, is more potent than amphetamine. Usefully, one may think of the amine group as enhancing stimulant-like properties.

#### Isopropyl Changes

An intact isopropyl side chain appears to be needed in order to maintain the potency of amphetamine. For example, changing the propyl to an ethyl chain creates phenylethylamine, an endogenous neuroamine (a metabolite of the monoamine oxidase inhibitor [MAOI] phenelzine) that has mood- and energy-enhancing properties but less potency and a much shorter half-life than amphetamine (Janssen et al. 1999).

## Aromatic Changes

Substitutions on the phenyl group are associated with a decrease in amphetamine-like properties. Interestingly, reduction of the phenyl to a cyclohexyl ring reduces the potency, but not the efficacy, of amphetamine properties. Unlike changes at the amine or isopropyl level, additions to the aromatic ring substantially alter the effects of the compound. The most common changes at the aromatic ring are of the methoxy type and are associated with hallucinogenic properties.

## Stereospecificity

In recent years there has been renewed interest in drugs that are pure stereoisomers, as opposed to racemic mixtures, especially with the release of dexamethylphenidate (the dextro isomer of methylphenidate) and escitalopram (the levo isomer of citalopram). In amphetamine isomers, it is true that the dextro form (i.e., dextro isomer, or dextroamphetamine) is almost twice as potent as the levo form (i.e., levo isomer, or levoamphetamine) in promoting wakefulness, but they are of equal potency in reducing cataplexy and rapid eye movement (REM) sleep ([Nishino and Mignot 1997](#)). The effect on dopamine reuptake is stereospecific; inhibition in rat brain, striatum, and hypothalamus has been found to be markedly different between the two isomers ([Ferris and Tang 1979](#)).

The clinical utility of stereospecificity is unclear. Urine levels of the levo isomer have been used to measure compliance in amphetamine-addicted patients prescribed dextroamphetamine for maintenance or detoxification; the logic is that the more levo isomer present in urine, the less compliance ([George and Braithwaite 2000](#)).

Perhaps the most clinically useful difference between amphetamine isomers involves their differential effects on reinforcement. Studies in rats have shown that the dextro isomer is four times more potent than the levo isomer in promoting lever pressing for intracranial stimulation ([Hunt and Atrens 1992](#)). However, that pure dextroamphetamine is better for the treatment of ADHD than, for example, the mixed salts of dextroamphetamine/amphetamine is neither obvious nor conclusively shown. In addition, the overall greater potency of the dextro form for central actions suggests that this form may have a higher potential for abuse.

## Pharmacological Profile

Amphetamines are noncatecholamine, sympathomimetic amines with central nervous system (CNS) stimulant activity that causes catecholamine efflux and inhibits the reuptake of these neurotransmitters (see subsection “Mechanism of Action” later in this section).

## Pharmacokinetics and Disposition

Amphetamine is highly lipid soluble and reaches peak levels in approximately 2 hours. Because of this lipid solubility, amphetamine has rapid distribution into

tissues and transit across the blood-brain barrier. The protein binding is highly variable, but the average volume of distribution ( $V_d$ ) is 5 L/kg.

The half-life of amphetamine is approximately 16–30 hours. On average, 30% of amphetamine is excreted unchanged.

## Mechanism of Action

The classic mechanism of action of amphetamine involves rapid diffusion directly into neuron terminals; through dopamine and norepinephrine transporters, amphetamine enters vesicles, causing release of dopamine and norepinephrine. The release of these neurotransmitters into the synapse mediates some of the psychological and motoric effects of amphetamine, including euphoria, increased energy, and locomotor activation.

## Side Effects and Toxicology

The side effects of amphetamines are predictable relative to their sympathomimetic pharmacology. The most common effects are nervousness, agitation, and decreased sleep. Serious adverse consequences have been observed with amphetamines and include arrhythmias, hyperpyrexia, rhabdomyolysis, and convulsions. Death, although uncommon, generally occurs only after the manifestation of one of these symptoms. Hallucinoses and psychosis are frequent complications of injected or inhaled amphetamines but are uncommon with oral intoxication.

Methamphetamine is more frequently associated with complications; because of its higher toxicity, it is not clear whether severe complications are dose dependent. For example, in a retrospective study of methamphetamine-related deaths in a large city, methamphetamine use was significantly associated with a higher risk of coronary artery disease, as well as a higher rate of subarachnoid hemorrhage, although it was of course impossible to determine whether the subjects were first-time users or chronic abusers ([Karch et al. 1999](#)). Of particular note in this study, however, was that blood levels of methamphetamine did not differ between the group in which methamphetamine was judged to be the cause of death and the group in which methamphetamine was detected but judged not to be related to the cause of death, suggesting that these toxicities are not necessarily dose dependent. Similarly, in one 5-year study, methamphetamine accounted for 43% of rhabdomyolysis cases in an emergency department setting.

Methamphetamine is more neurotoxic than amphetamine; it can cause destruction of dopaminergic neurons in the basal ganglia and thus is widely thought to increase the likelihood of future parkinsonism ([Guilarte 2001](#)). Although it is commonly believed that MDMA (3,4-methylenedioxy-*N*-methamphetamine; “Ecstasy”) is toxic primarily to serotonergic neurons ([Sprague et al. 1998](#)), evidence shows that it is also toxic to dopaminergic neurons ([Ricaurte et al. 2002](#)).

Seizures are fairly common in amphetamine abuse scenarios, especially with the more potent methamphetamine and hallucinogenic analogs.

Stimulant psychosis—often referred to as *paranoid psychosis*—is also common in amphetamine abuse scenarios because of the overwhelming presentation of the eponymous symptom. Visual hallucinations are also disproportionately common with amphetamine psychosis. Psychosis is often seen together with stereotypy. In humans, stereotypy can take many forms but usually is expressed as pacing, searching, or examining minute details.

## Drug-Drug Interactions

A comprehensive review found that drug interactions with amphetamine were mostly pharmacodynamic in nature ([Markowitz and Patrick 2001](#)); however, because a small portion of amphetamine metabolism occurs via the cytochrome P450 (CYP) 2D6 isoenzyme, those drugs that inhibit 2D6 metabolism can, theoretically, have the effect of increasing the plasma level of amphetamine.

---

## Lisdexamfetamine

---

Lisdexamfetamine dimesylate, a prodrug that on absorption is metabolized to dextroamphetamine and L-lysine, was approved in 2007 for the treatment of ADHD. Food does not affect absorption of lisdexamfetamine, but acidification of the urine results in more rapid clearance.

Two small studies in children found good efficacy and tolerability for lisdexamfetamine in the treatment of ADHD. A 4-week randomized, double-blind, forced-dose, parallel-group study compared lisdexamfetamine 30, 50, or 70 mg/day with placebo in children (ages 6–12 years) with ADHD ([Biederman et al. 2007b](#)). Efficacy, as measured by scores on the ADHD Rating Scale—Version IV (ADHD-RS-IV), the Conners Parent Rating Scale (CPR), and the Clinical Global Impression-Improvement (CGI-I) scale, was statistically superior to that of placebo for all dosages tested. A randomized, double-blind, placebo-controlled crossover study compared lisdexamfetamine with placebo and extended-release mixed amphetamine salts (Adderall XR) in 52 children (ages 6–12 years) with ADHD in an analog classroom setting ([Biederman et al. 2007a](#)). The study found comparable efficacy and safety for the active medications and superiority over placebo as measured by scores on the CGI-I scale and the Swanson, Kotkin, Agler, M-Flynn, and Pelham (SKAMP)–Department subscale.

In 420 adults, a 4-week forced-dose (30, 50, or 70 mg/day) study found lisdexamfetamine to have significantly greater efficacy over placebo as measured by ADHD-RS scores. Human liability studies have also found lower abuse-related drug-likeness scores compared with immediate-release D-amphetamine at equivalent dosages ([Najib 2009](#)).

In 2014, lisdexamfetamine was approved for the treatment of binge-eating disorder in adults. The registration trials involved more than 700 patients with moderate to severe binge-eating disorder. In a Phase II trial, subjects were randomly assigned to 30, 50, or 70 mg/day lisdexamfetamine or placebo for 3 weeks

and maintained at this dosage for an additional 8 weeks. Compared with placebo, the 50-mg/day and 70-mg/day dosages were more effective in reducing the total number of binge-eating days, were more likely to result in a remission of symptoms, and produced greater global improvement ([McElroy et al. 2015a](#)). Subsequent to that study, two Phase III trials have evaluated the efficacy and safety of lisdexamfetamine (target dosage of 50 or 70 mg/day as tolerated) versus placebo in adults ages 18–55 years with binge-eating disorder. Lisdexamfetamine at both dosages was more effective than placebo in reducing the total number of binge days. The active-treatment groups showed a reduction in binge-eating days from an average of 5 days/week to 1 day/week (versus a reduction to about 2 days/week in the placebo group). Compared with subjects who received placebo, those who received active treatment experienced greater overall improvement, as measured by the CGI-I score ([McElroy et al. 2016](#)).

Several preliminary studies suggested that lisdexamfetamine might be useful as an adjunctive treatment for major depressive disorder. [Trivedi et al. \(2013\)](#) found that 20–50 mg of lisdexamfetamine added to escitalopram for 6 weeks was superior to placebo in treating residual symptoms of depression. However, two subsequent Phase III randomized controlled trials failed to demonstrate a significant benefit for lisdexamfetamine over placebo in the adjunctive treatment of major depressive disorder. Still, there is some evidence that lisdexamfetamine may be more effective than placebo in treating executive function deficits in patients with major depressive disorder ([Madhoo et al. 2014](#)) and that it may have a role in the treatment of bipolar depression ([McElroy et al. 2015b](#)).

---

## Methylphenidate

---

### Structure–Activity Relations

Although methylphenidate has two chiral centers, only one contributes to its clinical effect. The D- and L-threo enantiomers are in a racemic mixture, although a single-isomer form of methylphenidate, dexamethylphenidate [(*R,R*)-(+)], is currently being marketed under the brand name Focalin. There are some differences in the pharmacological parameters of the two isomers, as described in the following subsection.

### Pharmacokinetics and Disposition

Methylphenidate is almost totally absorbed on oral administration (as is the single isomer dexamethylphenidate), although it is absorbed at a faster rate in the presence of food ([Chan et al. 1983](#)). Methylphenidate has low protein binding (15%) and is fairly short acting; the effects last approximately 4 hours, with a half-life of 3 hours. The primary means of clearance is through the urine, in which 90% is excreted.

## Mechanism of Action

Although it is both a norepinephrine and a dopamine reuptake inhibitor, methylphenidate appears to exert its effects primarily through its action on dopamine neurobiology. It blocks the dopamine transporter (DAT) and increases extracellular dopamine. The amount of extracellular dopamine increase varies greatly among individuals depending on the extent of both DAT blockade and baseline dopamine release.

## Side Effects and Toxicology

The common side effects of methylphenidate are similar to those of amphetamine and include nervousness, insomnia, and anorexia, as well as dose-related systemic effects such as increased heart rate and blood pressure. Overdose may lead to seizures, dysrhythmias, or hyperthermia ([Klein-Schwartz 2002](#)). At therapeutic dosages, discontinuation symptoms tend to be slight, but with chronic abuse, symptoms similar to those in amphetamine withdrawal, including lethargy, depression, and paranoia, can occur ([Klein-Schwartz 2002](#)).

## Drug-Drug Interactions

Although theoretically a substrate of CYP2D6, methylphenidate was found not to have any significant metabolism in humans via this enzyme ([DeVane et al. 2000](#)). The prescribing information ([Novartis 2007](#)) does cite methylphenidate's potential ability to inhibit the metabolism of warfarin, some antiepileptic agents, and tricyclic antidepressants (TCAs), and therefore caution should be observed. However, a review found that methylphenidate is relatively safe and has minimal drug-drug interactions, with the exception of concomitant MAOI use ([Markowitz and Patrick 2001](#)).

---

## Modafinil

---

Modafinil is the first U.S. Food and Drug Administration (FDA)-designated "wakefulness-promoting agent"; it is approved by the FDA for the treatment of excessive sleepiness associated with narcolepsy, sleep apnea, and residual sleepiness after standard treatment for shift-work sleep disorder ([Cephalon Inc. 2008](#)). As described below, modafinil does little to prevent or alter sleep when one is trying to do so; however, it appears to permit more stable wakefulness (i.e., reduced sleep propensity) when one is attempting to stay awake in the presence of elevated sleep pressure.

## Structure-Activity Relations

Modafinil (2-[(diphenylmethyl)sulfinyl]acetamide) exists in racemic form. Both stereoisomers appear to have the same activity in animals.

## Pharmacokinetics and Disposition

Modafinil, the primary metabolite of adrafinil, lacks many of the side effects found in adrafinil, such as increased liver enzymes, anxiety, and stomach pain. Modafinil is rapidly absorbed but slowly cleared. It has fairly high protein binding (60%) and a  $V_d$  of 0.8 L/kg. Its half-life is 11–14 hours.

The metabolism of modafinil is complex. In contrast to excretion of amphetamines, less than 10% of modafinil is excreted unchanged.

Metabolism is primarily via CYP3A4/5. It has been reported that modafinil also has in vitro capacity to induce CYP3A4 ([Robertson et al. 2000](#)), especially gastrointestinal 3A4. A clinically significant reduction of triazolam has been reported ([Robertson et al. 2002](#)).

## Mechanism of Action

The precise mechanism by which modafinil exerts its wakefulness-promoting effect in patients with excessive sleepiness due to narcolepsy is not yet known. Modafinil, given its efficacy in narcolepsy, is not surprisingly observed to increase c-fos activity of hypocretin cells, as well as in the tuberomammillary nucleus (which is primarily histaminergic), striatum, and cingulate cortex at higher dosages ([Scammell et al. 2000](#)). Additionally, in rats, an increase in histamine release in the anterior hypothalamus is seen ([Ishizuka et al. 2003](#)). However, modafinil's wakefulness-promoting effects were not decreased in histamine knockout mice ([Bonaventure et al. 2007](#)).

What may be an important aspect of the pharmacology of modafinil is its lack of effect on the neuroendocrine system. A comparison of healthy volunteers who were sleep deprived for 36 hours with those who received modafinil during sleep deprivation found no difference in cortisol, melatonin, or growth hormone levels ([Brun et al. 1998](#)).

## Side Effects and Toxicology

Modafinil appears to be well tolerated, with the most frequent side effects being headache and nausea. Side effects have been found to increase with dosages from 100 to 600 mg/day, and very high dosages (800 mg/day) have been found to be associated with higher rates of tachycardia and hypertension ([Wong et al. 1999](#)). Overall, only 5% of the patients in Phase III trials discontinued modafinil because of side effects ([Cephalon Inc. 2008](#)).

Modafinil appears to be fairly safe at high dosages. Reports indicate that 32 patients have safely taken 1,000 mg/day for more than 50 days; one individual safely took 1,200 mg/day for 21 consecutive days. Two patients took 4,000 mg and 4,500 mg, respectively, in a single dose and experienced only transient (<24 hours)

agitation and insomnia with mild elevations in heart rate and blood pressure ([Cephalon Inc. 2008](#)). There have been no reports of seizures with modafinil.

During the attempts to obtain FDA approval of modafinil for the treatment of ADHD, concerns arose over the possibility that modafinil may carry a risk of Stevens-Johnson syndrome. Three cases of drug-induced rash were reported during clinical trials ([U.S. Food and Drug Administration 2007](#)).

The package insert notes a risk of “serious rash, including Stevens-Johnson syndrome,” in adults and children and cautions that modafinil is not indicated for children. The insert cites a rash incidence of 0.8% in pediatric patients, with one case of possible Stevens-Johnson syndrome and one case of multiorgan hypersensitivity reported, and concludes with the statement that although there are no known predictive factors, benign rashes do occur, and modafinil should be discontinued if rash develops.

## Drug-Drug Interactions

As described earlier in this section, modafinil induces CYP3A4/5 and thus conceivably could lower the plasma concentrations of medications with substantial 3A4/5 metabolism. However, it is not clear if this induction is substantial only on the gastrointestinal cytochrome and is thus relevant only for other drugs undergoing significant first-pass metabolism.

Modafinil inhibits CYP2C19 in vitro ([Robertson et al. 2000](#)). It is prudent to assume that the effect of modafinil on the cytochrome system is not well characterized and to be vigilant for these potential drug-drug interactions.

---

## Armodafinil

---

Armodafinil, properly *l*-(*R*)-modafinil (or  $[-]$ -*R*)-modafinil), is the longer-acting isomer of racemic modafinil. In 2007, it received FDA approval for the same indications as modafinil—specifically, excessive sleepiness associated with narcolepsy, obstructive sleep apnea/hypopnea syndrome (OSAHS) as an adjunct to standard treatment, and shift-work sleep disorder (SWSD).

Armodafinil and racemic modafinil produce comparable peak plasma concentrations, although the peak for armodafinil occurs later than that for modafinil and is maintained for 6–14 hours postdose ([Dinges et al. 2006](#)).

Published data on armodafinil are still limited. Two 12-week double-blind studies using armodafinil 150 mg as an adjunct to continuous positive airway pressure (CPAP), both in patients who were otherwise stable except for some residual sleepiness ([Hirshkowitz et al. 2007](#)) and in patients who were still symptomatic ([Roth et al. 2006](#)), found improvements in wakefulness measures. Armodafinil also significantly improved the quality of episodic secondary memory (i.e., the ability to recall unrehearsed information). Whether this effect was due directly to the medication, to improved wakefulness, or to decreased hypoxia (as a function of

being more awake) is unclear. However, armodafinil did not adversely affect the CPAP or any other physiological parameters.

A 12-week double-blind study of armodafinil in narcolepsy found improvements similar to those seen with modafinil. These included improved wakefulness (as measured by the Maintenance of Wakefulness Test), improved Clinical Global Impression of Change (CGI-C) scores, and improvement in memory and attention. Armodafinil 150 mg/day and 250 mg/day were similarly effective ([Harsh et al. 2006](#)).

In SWSD, armodafinil 150 mg/day was tested against placebo in a 12-week study, showing significant prolongation of time to sleep onset and an improvement in overall clinical condition by CGI-C. Armodafinil had no effect on daytime sleep polysomnography ([Roth et al. 2005](#)).

---

## Clinical Uses of Stimulants and Wakefulness-Promoting Agents

---

Although stimulants have been used for many years in a number of clinical scenarios, double-blind, randomized controlled trials examining their safety, efficacy, and effectiveness in neurobehavioral disorders other than ADHD are relatively rare. Most of the support for their use comes from open-label studies and case series. Randomized trials of modafinil for neurobehavioral disorders with symptoms of sleepiness and fatigue are beginning to be published.

### Attention-Deficit/Hyperactivity Disorder

Multiple double-blind, placebo-controlled studies have shown the efficacy of stimulants for ADHD, and their use is well investigated in both adults and children ([Greenhill et al. 2002](#); [Wilens et al. 2002](#)). Some studies are aimed at showing the superiority of one preparation relative to another, although this approach is not always fruitful; for example, one study comparing various single-dose amphetamine preparations with one another and with placebo over 8 weeks found that they were all superior to placebo. However, immediate-release amphetamines had a faster onset but shorter duration of action; spansules, although much slower to take effect than the others, lasted several hours longer ([James et al. 2001](#)).

With respect to individual stimulants, all appear to be equally efficacious in the treatment of ADHD, but they have been reported to have different time courses. In a double-blind, double-control (placebo and methylphenidate) study, the mixed amphetamine salts of Adderall were found to exert their effects rapidly but to dissipate quickly over the course of the day, although Adderall lasted longer than methylphenidate ([Swanson et al. 1998](#)). Interestingly, higher doses of Adderall lasted longer than lower doses, indicating a dose-dependent effect in duration of action not found with methylphenidate. Thus, although stimulants may appear to be of equal efficacy overall, there is considerable variability in individual response to each stimulant.

The decision to choose amphetamines or methylphenidate for the treatment of ADHD is often based on the clinician's preference and degree of experience with the medication. At least one important blinded crossover study found that in performance tasks, both drugs were generally equally efficacious ([Efron et al. 1997](#)).

Modafinil is not FDA approved for the treatment of ADHD. A 4-week double-blind study with an 8-week open-label extension found modafinil to be efficacious across all ADHD rating subscales for the duration of the open-label extension ([Boellner et al. 2006](#)). Interestingly, 10% of the 220 children studied lost an average of 3 kg, while 4% gained the same amount. Another such double-blind study found significant efficacy with dosages of 300 mg/day, although heavier children ( $\geq 30$  kg) required 400 mg/day ([Biederman et al. 2006](#)). A pooled analysis of three trials (638 patients) found that modafinil produced similar and impressive improvements in ADHD rating scales between stimulant-naïve and prior-stimulant subgroups relative to placebo ([Wigal et al. 2006](#)). As in other studies, insomnia and headache were the most common, but infrequent, side effects. A 9-week trial ([Biederman et al. 2005](#)) found that almost half of patients (mean age 10 years, mean dosage 368 mg/day) were much or very much improved, and efficacy was seen in both inattentive and hyperactive subgroups and both school and home ratings. Some small but controlled trials ([Rugino and Samsock 2003](#); [Turner et al. 2004](#)) found efficacy with modafinil, and in one study ([Taylor and Russo 2000](#)), equivalence to dextroamphetamine was shown. Modafinil is currently indicated only for the treatment of excessive sleepiness associated with narcolepsy, OSAHS, and SWSD.

## Stroke and Traumatic Brain Injury

The results from studies on the effects of stimulants in patients who had strokes or traumatic brain injury are mixed. Although small early studies showed some superiority of amphetamine to placebo in improving motor function poststroke ([Crisostomo et al. 1988](#); [Walker-Batson et al. 1995](#)), a double-blind study found that 10 mg/day of amphetamine combined with physiotherapy in geriatric stroke patients was not superior to placebo plus physiotherapy in improving activities of daily living or motor function 5 weeks later ([Sonde et al. 2001](#)). Neither was amphetamine found to be superior to placebo in improving somatosensory training outcomes ([Knecht et al. 2001](#)). Modafinil also has not been consistently effective in the treatment of fatigue associated with traumatic brain injury ([Jha et al. 2008](#)). In contrast, relative to placebo, dextroamphetamine 10 mg/day significantly improved language recovery in poststroke aphasic patients when immediately coupled with a session of speech therapy; this effect was seen as quickly as within 1 week ([Walker-Batson et al. 2001](#)). A review lamented the lack of good data in brain-injured patients but did note that available data suggest that the bulk of stimulant efficacy may lie with its improvements in mood and cognitive processing ([Whyte et al. 2002](#)).

Although there is a dearth of placebo-controlled studies, there are some interesting reports in which stimulants were compared with antidepressants in patients with poststroke depression. One such study, comparing methylphenidate

with TCAs, found similar and significant response to both drugs, although the stimulant worked faster ([Lazarus et al. 1994](#)).

Modafinil has been reported to have some therapeutic efficacy in some types of brain injury. Two double-blind studies by the same group ([Saletu et al. 1990, 1993](#)) found modafinil effective in improving cognition and accelerating improvement in patients with alcoholic brain syndrome. In addition, there is some evidence that modafinil may help with cognition in patients with traumatic brain injury ([Dougall et al. 2015](#); [Maksimowski and Tampi 2016](#)).

## Cocaine and Stimulant Abuse

It may not be surprising that a double-blind study showed sustained-release dextroamphetamine to be superior to placebo in reducing cocaine use ([Grabowski et al. 2001](#)). However, similarly designed studies by the same authors did not find this effect with methylphenidate ([Grabowski et al. 1997](#)) or with risperidone ([Grabowski et al. 2000](#)). A double-blind, placebo-controlled study found that modafinil did not increase the euphoria or craving for cocaine; it may, in fact, have blunted the euphoria ([Dackis et al. 2003](#)). A double-blind, placebo-controlled study of 62 patients found that modafinil-treated patients had a longer duration of cocaine abstinence (>3 weeks), with no dropouts due to adverse events ([Dackis et al. 2005](#)). Likewise, a 48-day double-blind trial found that under controlled laboratory conditions, modafinil significantly attenuated self-administration and effects of cocaine ([Hart et al. 2008](#)). However, a large randomized controlled study of modafinil in the treatment of 210 subjects with DSM-IV-TR ([American Psychiatric Association 2000](#))-defined cocaine dependence did not find modafinil generally efficacious in improving abstinence from cocaine use ([Dackis et al. 2012](#)), although there was a trend for male patients receiving a modafinil dosage of 400 mg/day to be less likely to use cocaine. More study is needed to determine which, if any, patients with cocaine dependence might benefit from modafinil treatment.

## Alcohol Use Disorder

Basic research suggests that amphetamine appears to have an unexpected effect in alcohol use disorder. In rats, amphetamines reduced alcohol consumption during choice trials; this reduction was specific to alcohol intake, because amphetamine administration had no effect on rodents' intake of water ([Yu et al. 1997](#)). This effect of amphetamine on alcohol consumption may involve the neurobiology of reward systems. Much more research is needed to identify the mechanisms by which stimulants affect alcohol intake.

## Narcolepsy

Stimulants have traditionally been used for the treatment of excessive sleepiness associated with narcolepsy. Narcolepsy is characterized by excessive sleepiness that is typically associated with cataplexy and other REM sleep phenomena such as sleep

paralysis and hypnagogic hallucinations. Modafinil's approval for treatment of excessive sleepiness in narcolepsy was based on substantial evidence from large multicenter clinical trials ([Broughton et al. 1997](#); [U.S. Modafinil in Narcolepsy Multicenter Study Group 1998, 2000](#)). Modafinil is less disruptive of sleep than amphetamines and is rated as having a lower abuse potential ([Shelton et al. 1995](#)) (see [Table 44-1](#)). One study found that taking an extra dose (200 mg) at midday improved wakefulness in patients with narcolepsy without causing insomnia at night ([Schwartz et al. 2004](#)). Importantly, cataplexy—the sudden occurrence of muscle weakness in association with experiencing laughter, anger, or surprise—is responsive to amphetamines but not to modafinil ([Shelton et al. 1995](#)).

## Fatigue

The use of stimulants for the treatment of fatigue syndromes may seem intuitive, but evidence from large-scale controlled clinical trials to warrant this use is scant. In one of the only double-blind, placebo-controlled studies, men with HIV, depression, and fatigue had significantly less fatigue with dextroamphetamine (73% response) ([Wagner and Rabkin 2000](#)). Tolerance, dependence, and abuse were not observed, even across a 6-month open phase. A double-blind study of methylphenidate and pemoline in a similar group of 144 patients with HIV who had severe fatigue found both stimulants effective in improving fatigue and quality of life ([Breitbart et al. 2001](#)). [Rabkin et al. \(2011\)](#) found that a significant majority of HIV patients—including those with comorbid hepatitis C—reported an improvement in fatigue with armodafinil. Likewise, in a Phase III trial of modafinil treatment in 631 patients with cancer-related fatigue, [Jean-Pierre et al. \(2010\)](#) found that modafinil was more effective than placebo in helping patients with severe fatigue. However, modafinil did not separate from placebo in cancer patients with mild or moderate fatigue at baseline. Similarly, in a Phase III study of armodafinil 150 mg/day for 8 weeks in the treatment of cancer-related fatigue in multiple myeloma patients, armodafinil failed to separate from placebo ([Berenson et al. 2015](#)). In addition, no advantage was found for armodafinil in a controlled study of the treatment of brain radiation-related fatigue ([Page et al. 2015](#)).

Two controlled trials ([Adler et al. 2003](#); [Högl et al. 2002](#)) found modafinil effective in reducing excessive sleepiness in Parkinson's disease. Findings from open-label studies of modafinil for fatigue in multiple sclerosis ([Rammohan et al. 2002](#)) and myotonic dystrophy ([Damian et al. 2001](#)) suggest modafinil's utility in management of fatigue. A small double-blind crossover study of modafinil in myotonic dystrophy found a reduction in fatigue but no improvement on activity measures ([Wintzen et al. 2007](#)). This result would be consistent with modafinil's rather selective effect on wakefulness and minimal impact on motor or autonomic parameters. In the same vein, studies of modafinil in patients with fibromyalgia ([Schwartz et al. 2007](#)) and of armodafinil in patients with sarcoidosis ([Lower et al. 2013](#)) did find that the medications were useful in treating the fatigue associated with these disorders.

## Obstructive Sleep Apnea/Hypopnea Syndrome

There are two placebo-controlled studies of modafinil in the treatment of residual sleepiness in patients with DSM-IV-TR-defined obstructive sleep apnea ([Kingshott et al. 2001](#); [Pack et al. 2001](#)). The studies show modafinil's efficacy in treating the residual daytime sleepiness experienced by some OSAHS patients who were compliant in their use of CPAP treatment.

Importantly, modafinil's use was studied in—and should be limited to—the treatment of OSAHS only after CPAP has been instituted and optimized. OSAHS carries significant cardiovascular risks if the airway collapse during sleep is not treated appropriately with CPAP and related therapies. It is conceivable that lessened daytime sleepiness from use of modafinil might fool the patient into thinking that CPAP is unnecessary, thus posing a risk via the untreated underlying OSAHS.

## Obesity

That amphetamines are anorectic is well known; however, the extent of the effect may be overstated. [Bray and Greenway \(1999\)](#) summarized the studies of obesity treatments, wherein they cited a large review of more than 200 short-term (3-month) double-blind studies of various noradrenergic agents, including amphetamine and amphetamine derivatives. Patients taking stimulants were twice as likely as those taking placebo to lose 1 lb/week; however, the percentage of patients who lost 3 lb/week was quite small (10%). A small study found that high doses of amphetamine (30 mg) decreased overall caloric intake but did so primarily through a decrease in fat consumption; carbohydrate consumption actually increased ([Foltin et al. 1995](#)). This mild effect on appetite is important when considering the use of stimulants in elderly patients who lack both energy and motivation and have poor appetite.

## Depression

As described earlier in this chapter, the only large-scale randomized controlled trials of a stimulant in the treatment of depression have involved lisdexamfetamine. Whereas early controlled studies suggested a benefit from adjunctive lisdexamfetamine ([Trivedi et al. 2013](#)) in the treatment of depression, subsequent Phase III trials failed to demonstrate the efficacy of lisdexamfetamine in the treatment of residual depressive symptoms after selective serotonin reuptake inhibitor (SSRI) treatment.

Beyond the lisdexamfetamine data, the bulk of the evidence for the utility of stimulants in the treatment of depression derives from case series by [Feighner et al. \(1985\)](#) and [Fawcett et al. \(1991\)](#), which suggested the efficacy of stimulants combined with MAOIs and MAOI/TCA combinations as well as their safety in not causing hypertensive or hyperthermic crises, and case series by [Stoll et al. \(1996\)](#) and [Metz and Shader \(1991\)](#), in which a combination of stimulant and SSRI was used. Another case series argued for amphetamine's ability to augment an antidepressant effect in patients with only partial response, although the effects

were, not unexpectedly, primarily in improving fatigue and apathy ([Masand et al. 1998](#)).

In an open-label trial of depressed cancer patients, both amphetamine and methylphenidate were reported to improve depressive symptoms to the same extent, and effects were seen within 2 days. In this series, stimulants did not cause anorexia; in fact, they improved appetite in more than half of the patients studied ([Olin and Masand 1996](#)), suggesting that these agents are not contraindicated solely on the basis of concerns about anorexia.

In a review, [Orr and Taylor \(2007\)](#) noted the paucity of high-quality data and suggested a possible role for stimulants in depression, particularly as adjunctive agents, in specific patient subgroups.

The utility of modafinil in depressive states is still not well characterized, the majority of evidence being either anecdotal or retrospective. More work is likely forthcoming, but there are two studies that bear some examination. The mood-altering properties of modafinil were studied in 32 normal volunteers in a double-blind crossover inpatient study ([Taneja et al. 2007](#)). Modafinil had positive results on general mood, especially on alertness and energy measures, but also had a negative effect on feeling calm (i.e., increased anxiety).

A double-blind, placebo-controlled trial ([Dunlop et al. 2007](#)) examining the effects of modafinil initiated at the outset of treatment with an SSRI in depressed patients with fatigue found no difference in the primary outcome measure of the Epworth Sleepiness Scale but found some improvement in the hypersomnia items of the 31-item Hamilton Rating Scale for Depression. Two other controlled trials ([DeBattista et al. 2003](#); [Fava et al. 2005](#)) and two open-label trials ([DeBattista et al. 2001](#); [Menza et al. 2000](#)) suggest that modafinil may have some utility as an augmentation agent to antidepressants in depressed patients with fatigue or excessive sleepiness.

Both modafinil and armodafinil have shown some preliminary benefit in the treatment of bipolar depression. [Frye et al. \(2007\)](#) found that the addition of modafinil at dosages of 100–200 mg/day for 6 weeks to a standard mood stabilizer was more effective than the addition of placebo in 85 patients with bipolar depression. In a larger randomized controlled multicenter study ([Calabrese et al. 2010](#)), 257 patients with bipolar depression on either lithium or valproate were randomly assigned to receive augmentation treatment with 150 mg/day armodafinil or placebo. Armodafinil appeared to help some—but not all—patients with bipolar depression, and the differences between groups did not reach statistical significance. Likewise, a study of 399 bipolar depressed patients randomly assigned to receive adjunctive armodafinil or placebo for 8 weeks failed to demonstrate armodafinil's benefit on the primary outcome measure (mean change from baseline on the 30-Item Inventory of Depressive Symptomatology—Clinician-Rated [IDS-C30] total score) ([Frye et al. 2015](#)). However, armodafinil was efficacious on a number of secondary measures, including IDS-C30 remission and Global Assessment of Functioning.

# Negative Symptoms and Cognitive Deficits in Schizophrenia

Whereas positive symptoms of schizophrenia are often responsive to antipsychotics, negative symptoms and cognitive deficits are often not ([Tandon 2011](#)). Because the negative symptoms and cognitive impairments of schizophrenia are frequently more disabling than the positive symptoms, there has been interest in developing effective treatments for these symptoms and deficits. A number of studies have explored the efficacy of modafinil and armodafinil in the treatment of negative symptoms and cognitive deficits in schizophrenia, with mixed results. For example, whereas some studies have found that modafinil or armodafinil improves negative symptoms ([Arbabi et al. 2012](#); [Kane et al. 2010](#)) and working memory ([Scoriels et al. 2012](#)) in some schizophrenic patients, other studies have found no benefit ([Bobo et al. 2011](#); [Pierre et al. 2007](#); [Sevy et al. 2005](#)). Despite these mixed results, modafinil has been well tolerated in most studies in schizophrenia. By contrast, stimulants such as dextroamphetamine may worsen positive symptoms of schizophrenia and have been less commonly studied in the treatment of negative symptoms and cognitive impairments. Further study is required to determine the role of stimulants and wakefulness-promoting agents in schizophrenia.

---

## Conclusion

---

The safety and efficacy of stimulants for the treatment of ADHD have been established. Modafinil and armodafinil are also firmly established as efficacious wakefulness-promoting agents in narcolepsy, sleep apnea, and shift work sleep disorder. The utility of these drugs in other areas is being examined. Although there is intense interest in the potential use of stimulants and modafinil in other psychiatric and neurobehavioral conditions, controlled studies on their safety and efficacy are limited. It is unclear why stimulants have not been extensively investigated for clinical utility for indications other than the treatment of ADHD. The approval of armodafinil, as the newest of the wakefulness-promoting compounds, may perhaps spur further research. Well-designed large-scale controlled trials are needed to define and characterize the role of stimulants and modafinil in various psychiatric illnesses. It is hoped that this will be an area of continued interest and development, from the elucidation of the molecular mechanisms of stimulants and modafinil to the demonstration through controlled trials of their potential clinical safety and benefits.

This chapter is an update and revision of Ballas CA, Evans DL, Dinges DF: "Psychostimulants and Wakefulness-Promoting Agents," in *The American Psychiatric Publishing Textbook of Psychopharmacology*, 4th Edition. Edited by Schatzberg AF, Nemeroff CB. Washington, DC, American Psychiatric Publishing, 2009, pp. 843-860.

## CHAPTER 45

# **Electroconvulsive Therapy and Other Neuromodulation Therapies**

William M. McDonald, M.D.

Thomas W. Meeks, M.D.

Linda L. Carpenter, M.D.

W. Vaughn McCall, M.D., M.S.

Charles F. Zorumski, M.D.

Over the past several decades, electroconvulsive therapy (ECT) has been proven to be perhaps the most effective somatic treatment for mood disorders ([Kellner et al. 2012](#)). The continued use of ECT spurred more systematic research on its indications, techniques to maximize efficacy and minimize side effects, and understanding ECT's mechanism of action. In this chapter,

we review the history of ECT, the preclinical and clinical data on the mechanism of action of ECT, and the relevant literature related to the efficacy and side-effect burden of ECT. We also offer practical guidelines for the administration of ECT in treating various psychiatric disorders, including appropriate patient selection, stimulus settings and electrode placement, pretreatment medical evaluation, and management of the patient during acute, continuation, and maintenance courses of ECT. Finally, we discuss recent developments with nonconvulsive therapies such as transcranial magnetic stimulation (TMS) in relation to their efficacy in depression treatment and their utility as part of the neuromodulatory treatments.

---

## **Electroconvulsive Therapy**

---

### **History**

The development of ECT occurred at a time when few somatic treatments were available for psychiatric disorders and physicians were attempting to find treatments for severely ill psychotic patients. In 1935, Manfred Sakel (1900–1957) induced hypoglycemic episodes in psychiatric patients (using insulin shock therapy), and in the same year Lazlo Meduna (1896–1964) injected patients with pentylenetetrazol to induce convulsions in order to treat psychosis. Three years later, the Italian psychiatrists Ugo Cerletti (1877–1963) and Lucio Bini (1908–1964) used electroshock treatments to induce seizures. This treatment proved safer and easier to administer than chemically

induced seizures and replaced other methods of inducing seizures.

Modern psychopharmacology began with the discovery of lithium (1949) and iproniazid (1957) for the treatment of mood disorders and the synthesis of the first antipsychotic, chlorpromazine (1952); the first tricyclic antidepressant, imipramine (1959); and the first benzodiazepine, chlordiazepoxide (1960). The development of psychotropic medications was associated with a decline in the use of ECT from the 1960s to the 1980s, at which point the use of ECT began to increase, with data showing that more than 36,000 U.S. patients received ECT in 1986 ([Thompson et al. 1994](#)). However, the percentage of U.S. hospitals providing ECT declined by an estimated 43% between 1993 and 2009 ([Case et al. 2013](#)). Studies in Canada and Denmark have reported relatively stable rates of ECT use over the last 15–30 years ([Munk-Olsen et al. 2006](#); [Rapoport et al. 2006](#)), whereas decreasing rates of use have been reported in the United Kingdom and Australia ([Plakiotis et al. 2012](#); [Scott 2012](#)). The results of the Sequenced Treatment Alternatives to Relieve Depression (STAR\*D) study ([Rush et al. 2009](#)) and the Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) program ([Lieberman et al. 2005](#)) confirmed the limited effectiveness of psychopharmacology for major mental disorders and supported the continued clinical relevance of ECT for those patients whose symptoms do not respond to medication management ([Insel and Wang 2009](#); [McCall 2007](#)).

Since the 1980s, the safety of ECT has improved significantly with the introduction of sophisticated cardiopulmonary and electroencephalographic monitoring, the development of better anesthetic agents, and the adoption of the brief-pulse stimulus machine. Today, ECT is

arguably the fastest, most effective treatment for mood disorders. ECT is also one of the safest procedures performed under general anesthesia, with a mortality rate reported at 0.002% or less ([Watts et al. 2011](#)).

## Mechanism of Action

### Anticonvulsant Hypothesis

One of the most popular theories on the mechanism of action of ECT is that the antidepressant efficacy is directly correlated with the anticonvulsant effect of ECT. That is, the therapeutic effect of ECT is proportional to an increase in the seizure threshold during ECT. This theory is based on the fact that a course of ECT results in an increase in seizure threshold and a decrease in seizure duration ([Sackeim 1999](#)) and focuses on changes in neurotransmitter systems and intracellular biochemical processes related to the seizure threshold.

$\gamma$ -Aminobutyric acid (GABA) is the predominant inhibitory transmitter in the brain and is a target for multiple anticonvulsant drugs (e.g., barbiturates, benzodiazepines). Data from animal studies indicated increases in the threshold for bicuculline- and pentylenetetrazol-induced seizures following a series of electroconvulsive shock (ECS) treatments ([Nutt et al. 1981](#); [Płaźnik et al. 1989](#)). Because bicuculline and pentylenetetrazol act by inhibiting GABA<sub>A</sub> receptors, these findings suggest that ECT results in changes in GABAergic inhibition. Additionally, GABA levels increase in certain central nervous system (CNS) regions after ECS in laboratory animals ([Green et al. 1982](#)), and evidence from magnetic resonance spectroscopy indicates that ECT increases GABA levels in the occipital cortex in

humans ([Sanacora et al. 2003](#)). These changes in GABA levels suggest that there may be an increase in tonic inhibition after repeated seizures, and effects on GABA-mediated tonic inhibition are increasingly recognized as an important aspect of several neuroactive drugs ([Farrant and Nusser 2005](#)). In line with this research is the finding that the most consistent biological marker for ECT response has been increased frontal delta activity (i.e., postictal depression) shown on the electroencephalogram (EEG) after ECT ([Azuma et al. 2007](#); [Mayur 2006](#)), which is associated with decreased cerebral blood flow in the immediate postictal period ([Nobler et al. 1993](#)).

## **Antidepressant Medication and the Effects of Electroconvulsive Therapy on Mood Disorders**

The efficacy of anticonvulsants as mood stabilizers supports the anticonvulsant hypothesis; this hypothesis is appealing in that it can explain the therapeutic effects of ECT in both mania and depression ([Sackeim 1994, 1999](#)). Yet most antidepressants are not anticonvulsants, and researchers have investigated other common mechanisms of action for ECT and antidepressant medication to determine the therapeutic effects of ECT.

There are several common threads in the neurotransmitter changes induced by ECT and antidepressant medication. ECT, like antidepressant pharmacotherapy, has been reported to normalize hypothalamic-pituitary-adrenal (HPA) axis perturbations associated with major depressive disorder ([Yuuki et al. 2005](#)). However, a more productive area of research has focused on determining how a course of ECT affects biogenic amines. Of interest is the finding that certain

antidepressants cause  $\alpha_1$ -adrenergic receptor subsensitivity, and similar effects are observed with ECS ([Nutt and Glue 1993](#)). ECS has multiple other effects on the adrenergic system, including increased norepinephrine turnover, increased  $\alpha_1$ -adrenergic receptor sensitivity, and possibly decreased presynaptic  $\alpha_2$ -adrenergic receptor sensitivity. ECS also enhances the function of the serotonin system, producing increased behavioral responses to serotonin agonists and possibly increases in 5-hydroxytryptamine type 2 (5-HT<sub>2</sub>) receptor binding in the cerebral cortex ([Fochtmann 1994](#); [Nutt and Glue 1993](#); [Sackeim 1994](#)). Thus, 5-HT<sub>2</sub> receptor downregulation, like  $\alpha$ -adrenergic receptor subsensitivity, may be a mechanism common to several antidepressant treatments.

One of the more intriguing avenues for understanding the effects of ECT is the literature on the neurocircuitry of mood regulation and depression. This circuitry involves connections between and within regions of the prefrontal cortex, anterior cingulate gyrus, subgenual prefrontal cortex, anterior thalamus, and more traditional limbic structures (hippocampus and amygdala) ([Drevets 2000](#); [Seminowicz et al. 2004](#)). Evidence now indicates structural changes including cell loss (glia and possibly neurons) in several of these regions in subtypes of depression ([Harrison 2002](#)). It also appears that different antidepressant treatments may differentially affect metabolism in this circuit. Effective treatment with paroxetine appears to increase metabolism in frontal regions while decreasing metabolism in the hippocampus, whereas cognitive-behavioral therapy results in the opposite effects ([Goldapple et al. 2004](#); [Seminowicz et al. 2004](#)). ECT, in contrast, diminishes metabolism in both prefrontal cortex

and hippocampus ([Nobler et al. 2001](#)). Although it is too early to draw firm conclusions about these observations, it is intriguing that chronic deep brain stimulation (DBS) targeted toward the subgenual prefrontal region appears to be effective in a small sample of patients with treatment-resistant chronic depression ([Mayberg et al. 2005](#)), further implicating neurocircuitry changes in the biology of depression.

Evidence suggests that several antidepressant treatments, including ECS, have neurotrophic effects and result in neurogenesis in the dentate gyrus of adult rodents ([Madsen et al. 2000](#); [Malberg et al. 2000](#); [Scott et al. 2000](#)). These effects may result from changes in brain-derived neurotrophic factor (BDNF) and the receptor tyrosine kinase (TRK<sub>B</sub>) through which BDNF exerts its actions, as well as from the treatment's effects on the adenylate cyclase intracellular signaling system, including the downstream effector cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB) ([Duman and Vaidya 1998](#); [Nestler et al. 2002](#); [Schloss and Henn 2004](#)).

Other evidence suggests that the new neurons produced in the dentate gyrus of adult rodents have the properties of functional neurons and participate in synaptic transmission ([Song et al. 2002](#)), suggesting that antidepressant treatments, including ECT, may ultimately enhance hippocampal function. Hippocampal changes appear to be accompanied by increases in local angiogenesis and blood flow in specific subregions of the hippocampus ([Hellsten et al. 2005](#); [Newton et al. 2006](#)). Whether effects on neurogenesis are important for the therapeutic effects of ECT and other antidepressant treatments remains speculative, although elegant studies in rodents provide

evidence that neurogenesis is important for at least some behavioral effects of medications ([Santarelli et al. 2003](#)). Whether similar neurotrophic effects occur with ECT in humans is uncertain. However, studies that used magnetic resonance spectroscopy to monitor regional changes in the glutamate-to-glutamine ratio (Glx), a marker of local intracellular excitatory transmitter metabolism ([Hasler et al. 2007](#)), indicated that depressed subjects have low Glx values that increase to normal values with effective ECT ([Michael et al. 2003](#); [Pfleiderer et al. 2003](#)). Changes in Glx in depression treated with ECT may reflect alterations in glial function in the circuitry underlying depression.

Recent efforts to identify mechanisms contributing to the effects of ECT and antidepressant drugs have included the use of microarrays to study gene expression in multiple brain regions. Although these studies are in their infancy, some evidence indicates that rapidly acting treatments like ECT result in changes primarily in the catecholaminergic system, whereas treatments that act more slowly, such as fluoxetine, act predominantly on the serotonergic system. These studies also show strong effects of ECT on BDNF and transcripts encoding proteins involved in hippocampal synaptic plasticity ([Conti et al. 2007](#)). Follow-up studies examining protein expression and downstream functional effects will be important in determining their relevance to ECT's clinical actions.

## Indications and Efficacy

### Depression

The summary statement by the American Psychiatric Association Task Force on Electroconvulsive Therapy

([American Psychiatric Association 2001](#)) has supported the efficacy and safety of ECT. A meta-analysis of randomized controlled trials (RCTs) performed by the [UK ECT Review Group \(2003\)](#) confirmed the following about the efficacy of ECT for major depressive disorder:

- ECT is more efficacious than sham ECT (shown in six RCTs; effect size = 0.91).
- ECT is more efficacious than antidepressant pharmacotherapy (18 RCTs; effect size = 0.80).
- Aspects of ECT associated with a positive response include higher total dose and bilateral electrode placement (although many studies likely underdosed patients with unilateral ECT).

Given these data, ECT should no longer be considered a treatment of last resort ([Beale and Kellner 2000](#); [Kellner et al. 2005](#)). Instead, ECT should be viewed as a potential first-line treatment when a rapid clinical response is essential in severely ill patients (e.g., those with active suicidal ideation, catatonia, or a compromised medical condition related to depression such as dehydration or malnutrition), when the patient has a history of a positive response to ECT, or when the patient (or surrogate decision maker) requests ECT over other treatment options.

ECT exerts its antidepressant effects more rapidly than pharmacotherapy does, and research has confirmed a rapid resolution of suicidal ideation with ECT ([Kellner et al. 2005](#); [Patel et al. 2006](#)). [Beale and Kellner \(2000\)](#) argued that delaying the use of ECT until multiple medication trials have failed does not take into account the tolerability and efficacy of modern ECT and may lead to needless suffering on the part of the patient. They pointed out that

antidepressant treatment algorithms place ECT as a tertiary treatment (e.g., [Rush and Thase 1997](#)) instead of recommending that ECT practitioners be consulted early in the treatment process to determine whether ECT would be appropriate therapy.

Surveys show that patients who have received ECT rate it as a highly effective treatment ([Parker et al. 2001](#)) and that 85% of the patients who have received ECT would agree to a second course of ECT if needed ([Bernstein et al. 1998](#)). ECT-related relief of depressive symptoms also has been associated with long-term improvements in health-related quality of life, an increasingly important outcome measure in medical research ([McCall et al. 2006](#)).

**Predictors of response.** Positive predictors of response include increasing age ([Dombrovski et al. 2005](#); [O'Connor et al. 2001](#)) and the presence of psychotic or catatonic symptoms ([Birkenhäger et al. 2005](#); [Buchan et al. 1992](#); [Petrides et al. 2001](#)). Several studies have reported that patients with longer current episodes of depression ([Dombrovski et al. 2005](#)) or personality disorders (e.g., borderline personality disorder) ([Feske et al. 2004](#); [Parker et al. 2001](#); [Rasmussen 2015](#)) are less likely to respond to ECT. Medication resistance also has been found to correlate with lack of response to ECT ([Heijnen et al. 2010](#); [Sackeim et al. 2001a](#)).

Patients with depression complicated by dysthymia (i.e., double depression) appear to respond to ECT to the same extent that patients without dysthymia do ([Prudic et al. 1993](#)). Attempts to link subtypes of depression (e.g., melancholic vs. atypical, unipolar depression vs. depression associated with bipolar disorder) to ECT response generally have not identified differences. However, response by

session 3 of ECT may predict long-term efficacy in relieving depression ([Tsuchiyama et al. 2005](#)).

Among persons with comorbid major depressive disorder and posttraumatic stress disorder (PTSD), those with impaired suppression on the dexamethasone suppression test responded better to ECT than did those with normal or excessive suppression ([Watts and Groft 2010](#)). Genetic variants related to dopamine functioning (catechol-*O*-methyltransferase and dopamine type 2 receptors) also may play a role as moderators of response to ECT ([Anttila et al. 2008](#)).

[Coffey et al. \(1989\)](#) found that elderly patients referred for ECT had a greater number of structural abnormalities observed on magnetic resonance imaging (MRI) scans of the brain (e.g., deep white matter, basal ganglia, and periventricular hyperintensities) compared with age-matched control subjects. Although age is positively correlated with response to ECT, these white matter abnormalities, in addition to medial temporal lobe atrophy, may decrease the response to ECT in an individual older patient ([Hickie et al. 1995](#); [Oudega et al. 2011](#); [Steffens et al. 2001](#)) and increase the risk of interictal delirium ([Figiel et al. 1990](#)).

## Mania

Anecdotal reports and case studies suggest that ECT is beneficial in the treatment of mania associated with bipolar disorder ([Fink 2001, 2006](#)). In a prospective controlled trial, [Small et al. \(1988\)](#) compared the efficacy of ECT with that of lithium in the treatment of mania. Patients who received ECT improved more during the first 8 weeks of treatment than did patients who received lithium.

Nevertheless, after 8 weeks of treatment, ECT and lithium were comparable in efficacy.

A double-blind RCT of bifrontal and bitemporal ECT in acute mania also confirmed the efficacy of ECT in mania ([Hiremani et al. 2008](#)). In addition, patients with mixed symptoms of depression and mania responded particularly well to ECT ([Gruber et al. 2000](#); [Medda et al. 2010, 2014](#); [Valentí et al. 2008](#); [Vieta 2005](#)). Given the benefit of anticonvulsant medications in treating mania and the evidence that ECT may exert its therapeutic effect by raising the seizure threshold ([Sackeim 1999](#)), the efficacy of ECT for mania is not surprising. Catatonia secondary to mania represents another clinical scenario in which ECT may offer advantages in efficacy and rapidity of response compared with pharmacotherapy ([Taylor and Fink 2003](#)).

Challenges specific to treating mania with ECT include the following:

- Concomitant use of anticonvulsants, which may interfere with seizure induction in ECT
- Reports of prolonged seizures and delirium when ECT is given with lithium ([Sadananda et al. 2013](#); [Sartorius et al. 2005](#)), although other researchers have reported safe coadministration of ECT and lithium ([Dolenc and Rasmussen 2005](#); [Thirthalli et al. 2011](#))
- Decreased likelihood that manic (vs. depressed) patients will voluntarily consent to ECT treatment

Despite a rapid increase in studies evaluating alternative mood-stabilizing medications, including newer anticonvulsants and atypical antipsychotics, there is a relative lack of research comparing the potential benefits of ECT in the acute and maintenance treatment of bipolar

disorder ([Fink 2001](#); [Keck et al. 2000](#)). This is regrettable given the advantages of ECT as a mood stabilizer that can effectively treat both the manic and the depressed phases of the illness. ECT has been given safely to children with intractable mania ([Hill et al. 1997](#)) and to patients with dementia and comorbid mania ([McDonald and Thompson 2001](#)). ECT also may have an important role in the treatment of mania during pregnancy, given the potential teratogenic effects of many anticonvulsant medications as well as the potential harm to both the mother and the fetus from a prolonged affective episode ([Spodniakova et al. 2014](#)).

It is unclear whether unilateral ECT is as effective as bilateral ECT in the treatment of mania. [Hiremani et al. \(2008\)](#) found both bifrontal and bitemporal ECT to be effective for mania with equivalent side-effect burden, although patients had a more rapid improvement with bifrontal electrode placement. Future research is needed to clarify the role of ECT in the treatment of mania, although clear evidence indicates that ECT is an effective treatment and should be included in any algorithm of therapy for treatment-resistant, severely disabling, catatonic, or delirious mania ([Jacobowski et al. 2013](#); [Nivoli et al. 2012](#)).

## Schizophrenia

With the introduction of clozapine and the atypical antipsychotics, ECT has become a third-line treatment for schizophrenia in the United States, but ECT may be a first-line treatment for schizophrenia in some Eastern Hemisphere countries such as India and China (e.g., [McDonald 2012](#)). ECT continues to have an important role in the treatment of acute psychotic episodes, catatonic schizophrenia, and neuroleptic malignant syndrome

([Matheson et al. 2010](#); [Pompili et al. 2013](#); [Tharyan and Adams 2005](#)). Case reports of ECT in more chronic and treatment-resistant cases support the role of ECT in the treatment of schizophrenia ([Biedermann et al. 2011](#); [Chanpattana and Kramer 2003](#); [Chanpattana and Sackeim 2010](#); [Cupina et al. 2013](#); [Pawelczyk et al. 2014](#); [Pompili et al. 2013](#)).

ECT is particularly beneficial in the treatment of positive symptoms of schizophrenia and is less effective in decreasing negative symptoms ([Chanpattana and Sackeim 2010](#); [Pawelczyk et al. 2014](#)). ECT also has been shown to be effective in augmenting antipsychotic treatment in treatment-resistant schizophrenia ([Painuly and Chakrabarti 2006](#); [Ravanić et al. 2009](#)). A randomized trial found bilateral ECT to be effective as an add-on to clozapine for treatment-refractory psychosis in schizophrenia, with a 50% response rate in this difficult-to-treat population ([Petrides et al. 2015](#)).

ECT combined with antipsychotic therapy also may be effective in the management of aggressive behavior in patients with schizophrenia ([Hirose et al. 2001](#)) as well as for maintenance treatment of schizophrenia ([Chanpattana et al. 1999](#)).

There has been research to support bifrontal (as opposed to bitemporal) electrode placement as providing better treatment response and tolerability in schizophrenia, although the data are limited ([Phutane et al. 2013](#)).

Catatonic schizophrenia is very responsive to ECT ([Fink 2013](#); [van Waarde et al. 2010](#)), and ECT can be an important treatment when benzodiazepines are ineffective and symptoms do not respond to antipsychotics or when antipsychotics are relatively contraindicated because of an

unclear diagnosis of catatonia versus neuroleptic malignant syndrome ([Rosebush and Mazurek 2010](#)).

The recommendations of the American Psychiatric Association Task Force on Electroconvulsive Therapy ([American Psychiatric Association 2001](#)) state that ECT is an effective treatment for schizophrenia in the following clinical conditions: 1) during acute onset of symptoms, 2) when the catatonic subtype of schizophrenia is present, and 3) when there is a history of a positive response to ECT.

## **Other Medical and Psychiatric Disorders**

ECT can be a lifesaving treatment for patients with catatonia regardless of the etiology, including catatonia resulting from a medical disease (e.g., systemic lupus erythematosus), neuroleptic malignant syndrome, schizophrenia, autism spectrum disorders, bipolar disorder, and major depressive disorder ([Luchini et al. 2015](#); [Rosebush and Mazurek 2010](#)). Patients with developmental delay complicated by catatonia and self-injurious behavior have shown improvements in catatonic symptoms and self-injurious behavior with ECT ([Wachtel et al. 2013](#)), as have patients with developmental delay and comorbid mood symptoms ([Aziz et al. 2001](#); [van Waarde et al. 2001](#)).

A recent matched case-control study of more than 40,000 patients with PTSD and major depressive disorder (MDD) found that compared with antidepressant therapy alone, ECT combined with antidepressants was associated with a significant reduction in PTSD and MDD symptoms as well as a decrease in completed suicides and cardiovascular and all-cause mortality ([Ahmadi et al. 2016](#)). Citing a case report of a decrease in PTSD symptoms when traumatic events were recalled immediately prior to each ECT session ([Gahr et al. 2014](#)), [Andrade et al. \(2016\)](#) hypothesized that

ECT is effective because the treatment impairs reconsolidation of reactivated, emotionally aversive memories.

Limited evidence suggests that ECT may relieve symptoms associated with obsessive-compulsive disorder (OCD) ([A.Y. Liu et al. 2014](#); [Maletzky et al. 1994](#); [Thomas and Kellner 2003](#)) and schizophrenia complicated by OCD ([Lavin and Halligan 1996](#)).

Because the administration of ECT raises the seizure threshold, ECT can interrupt status epilepticus ([Cline and Roos 2007](#); [Fink et al. 1999](#); [Lisanby et al. 2001](#); [Shin et al. 2011](#)) and treat intractable seizures ([Regenold et al. 1998](#)).

Case reports and retrospective reviews have found that ECT can alleviate behavioral and psychological symptoms of dementia, including associated depression, psychosis, and agitation; such patients would be at increased risk for delirium during the acute course of ECT, but the limited existing evidence does not indicate significant worsening of the underlying dementia ([X. Liu et al. 2014](#); [Rodríguez-Sosa et al. 2013](#); [Tang et al. 2014](#); [Ujkaj et al. 2012](#)).

ECT is effective in treating psychosis and depression in patients with Huntington's disease ([Cusin et al. 2013](#)). ECT also has been shown to be an effective treatment for the motor symptoms of Parkinson's disease ([Faber and Trimble 1991](#); [Kellner et al. 1994](#); [Rasmussen and Abrams 1991](#)), and a meta-analysis of five studies confirmed that ECT acutely improves global motor functioning in patients with Parkinson's disease, with a notable effect size of 1.68 ([Fregni et al. 2005](#)). These reports have included patients with and without psychiatric illnesses; ECT improves the motor symptoms of Parkinson's disease independently of its effects on the patient's mood. Favorable predictors of response include advanced age, severe disability (on-off

syndromes), and painful dyskinesias. Reductions in the symptoms of Parkinson's disease tend to occur during the first several sessions of ECT. However, the effects of ECT are not permanent and usually last from several days to several months, although prolonged improvement has been reported in a few patients. Maintenance ECT also has been shown to be effective for up to 4 years in treating the motor symptoms of Parkinson's disease ([Aarsland et al. 1997](#); [Wengel et al. 1998](#)).

Autoimmune disorders with comorbid depression and psychosis have been successfully treated with ECT, including anti-*N*-methyl-D-aspartate receptor encephalitis ([Kuppuswamy et al. 2014](#)) and systemic lupus erythematosus ([Tan and Tan 2013](#)).

ECT may exert some analgesic effects independent of its effects on mood, as evidenced in a trial with positive results that used ECT to treat fibromyalgia ([Usui et al. 2006](#)). ECT has also been shown to be effective in the treatment of both mood symptoms and pain in patients with complex regional pain syndromes ([McDaniel 2003](#)).

## **Electroconvulsive Therapy Use During Pregnancy**

According to a joint report by the American Psychiatric Association and the American College of Obstetricians and Gynecologists ([Yonkers et al. 2009](#)), ECT is an effective, safe treatment for women who experience severe manic and/or depressive symptoms during pregnancy. As with pharmacotherapy, ethical concerns limit randomized prospective trials to assess the efficacy and safety of ECT in pregnancy, although ECT has been safely used in all three trimesters ([Rabheru 2001](#)).

A review of 339 case reports from 1941 to 2007 identified 25 cases of fetal complications during ECT (of which fewer than 50% were deemed possibly or likely related to ECT) and 20 cases of maternal complications (of which 90% were deemed possibly or likely related to ECT) ([Anderson and Reti 2009](#)). The efficacy rates for ECT in these case reports were in keeping with efficacy rates for ECT in nonpregnant patients (61% for schizophrenia, 84% for depression).

The risks of administering ECT during pregnancy have been reviewed by [Rabheru \(2001\)](#). Possible strategies for mitigating risk of ECT during pregnancy include obstetrics consultation and performance of the procedure in facilities equipped to deal with obstetrical emergencies. Physiological issues in pregnancy that could affect risks include delayed gastric emptying, aortocaval compression causing placental insufficiency, uterine restriction on respiratory ventilation when supine, and seizure-induced elevations in oxytocin with subsequent premature uterine contractions. Use of antacids, adequate hydration, elevation of the right hip, and availability of tocolytic therapy if needed are strategies to address these respective pregnancy-specific issues in ECT administration ([Saatcioglu and Tomruk 2011](#)).

## Stimulus Dosing in Electroconvulsive Therapy for the Treatment of Depression

Questions about the proper management of the electrical stimulus have been central to the science and practice of ECT. Cerletti and Bini modeled ECT on the success of

pharmacologically induced convulsive therapy and assumed that the stimulus should be convulsive. Interestingly, the first ECT session in 1938 involved two subconvulsive stimulations before Cerletti and Bini increased the stimulus intensity to produce a convulsion ([Endler 1988](#)). Thus, the first ECT session was a “titrated” ECT session involving the serial application of increasing stimulus intensities passing from the subconvulsive range through the convulsive threshold. Issues in stimulus dosing that have been considered since that time include the following:

- Whether the stimulus should be subconvulsive or convulsive
- What the optimal stimulus waveform is
- If a convulsive stimulus is desired, to what degree the stimulus intensity should be in excess of the convulsive threshold
- Which physiological parameters, if any, provide useful feedback to continuously refine stimulus dosing throughout the ECT course

## **Convulsive, Subconvulsive, and Sham Stimulation**

The use of nonconvulsive electrical stimulation to treat psychiatric disorders preceded the introduction of ECT by decades. Most of the treatments involved administering static electricity to parts of the body including but not limited to the head ([Grover 1924](#)). The availability of commercial ECT devices did not lead to the immediate replacement of subconvulsive stimulation with convulsive stimulation. Instead, some practitioners used the devices to deliver lengthy (several minutes long) subconvulsive cranial stimulation. However, it became clear that subconvulsive

stimulation was associated with a *poorer* outcome than conventional psychotherapy in patients in the depressive/anxious spectrum, and the practice of treating patients with subconvulsive stimuli decreased ([Hargrove et al. 1953](#)). Now, many years later, the use of repetitive transcranial magnetic stimulation (rTMS) has reopened the question of whether subconvulsive stimuli are an effective treatment for depression; these data are reviewed in a later section (see “Subconvulsive Stimulation Therapies: rTMS and VNS”). The elements of modified ECT (including muscle relaxation and general anesthesia) were described early in the history of ECT. The wide-scale adoption of these modifications raised new questions as to whether seizure is central to the antidepressive efficacy of ECT or whether anesthesia alone would be just as effective. The Northwick Park trial ([Johnstone et al. 1980](#)) and the Leicestershire trial ([Brandon et al. 1984](#)) are examples of two “sham” ECT studies in which anesthesia alone was compared with real ECT. It was convincingly demonstrated that real ECT is more efficacious, especially for the most severe forms of depression ([Brandon et al. 1984](#); [Johnstone et al. 1980](#)). The efficacy of ECT was clearly linked to the production of a seizure. Neither the use of anesthesia alone without the electrical stimulus nor the use of subconvulsive stimuli appears to have real benefit in the treatment of depression.

## **Stimulus Waveform**

Given that a convulsive stimulus is necessary for the antidepressive effects of ECT, a nearly infinite number of variations are available for formulating the stimulus waveform. The earliest ECT devices delivered a sinusoidal stimulus. Other waveforms available on early ECT devices included the “chopped” sine wave, the unidirectional pulse

square wave, and the alternating brief-pulse square wave. Although some investigators suspected that sine wave stimuli might produce slightly better antidepressive effects compared with brief-pulse stimuli, that idea became untenable when a randomized study showed that sine wave ECT produced more memory side effects than brief-pulse ECT, irrespective of the placement of the stimulating electrodes ([Weiner et al. 1986b](#)).

This finding of greater cognitive side effects with sine wave ECT was replicated in an efficacy study using a prospective cohort design, which showed that compared with brief-pulse stimulation, sine wave stimulation was associated with a slowing of reaction time that persisted for at least 6 months after ECT ([Sackeim et al. 2007](#)). The more severe cognitive side effects produced by sinusoidal stimuli may be explained by the slower rise time for each sine wave cycle as compared with the brief-pulse cycle. Consequent to the slower rise time, much of the sine wave stimulus is subconvulsive and thus presumably adds nothing to the therapeutic effect of ECT, adding only to cognitive side effects. The steep rise in the brief-pulse waveform allows for the entire stimulus to be above the convulsive threshold (suprathreshold). Because much of the sine wave stimulus is nonproductive, being in the subconvulsive range, it would be predicted that brief-pulse stimuli would be more efficient, requiring a stimulus of smaller magnitude to produce a seizure. *Standard* brief-pulse stimuli are defined by a pulse duration of 1-2 milliseconds, whereas *ultrabrief*-pulse stimuli are defined by a pulse duration of less than 0.50 millisecond. In [1980](#), [Weiner](#) showed that standard brief-pulse stimuli could induce a seizure with only one-third of the energy required with sine wave stimuli. Standard brief-pulse ECT devices have currently replaced

sine wave devices in the United States ([Farah and McCall 1993](#)).

Devices using ultrabrief-pulse stimuli have the advantage of improving the efficiency of seizure induction. [Abrams \(2002\)](#) estimated that it takes only about 0.25 millisecond to initiate neuronal depolarization, and that longer pulse widths are inefficient and waste electrical charge. The total energy output of these ultrabrief-pulse modalities is the same as the total energy output of the standard brief-pulse widths; thus, as the stimulus pulse widths are shortened, the stimulus trains are lengthened. Ultrabrief-pulse widths may have an advantage because shorter pulse widths and longer pulse trains have been shown to elicit seizures with a smaller electrical charge and therefore may have fewer cognitive side effects ([Sackeim et al. 2008](#)).

Several recent studies have assessed the efficacy and side-effect profile of brief-pulse versus ultrabrief-pulse width right-unilateral ECT. In a prospective study comparing ultrabrief-pulse right-unilateral ECT (0.3 millisecond;  $n=74$ ) versus brief-pulse right-unilateral ECT (1.0 millisecond;  $n=22$ ) in depressed patients, [Loo et al. \(2008\)](#) found similar depression response rates in the two groups (albeit a slower rate of response in the ultrabrief-pulse right-unilateral ECT group), with better cognitive outcomes in the ultrabrief group. In a prospective randomized trial of high-dose right-unilateral ECT in 87 depressed inpatients, [Spaans et al. \(2013b\)](#) found that patients receiving ultrabrief-pulse ECT were significantly less likely to achieve remission—and required significantly more treatments to do so—compared with patients receiving brief-pulse ECT. A retrospective study in 150 subjects pooled from three research samples found that fewer treatments were needed with brief-pulse than with

ultrabrief-pulse right-unilateral ECT and that remission rates were significantly higher with brief-pulse ECT ([Loo et al. 2013](#)). Generally, researchers have found that ultrabrief-pulse right-unilateral ECT produced fewer neurocognitive effects (specifically on autobiographical memory) compared with brief-pulse treatment ([Loo et al. 2008](#); [Mayur et al. 2013](#); [Verwijk et al. 2012](#)) or that side effects for the two types were similar ([Spaans et al. 2013b](#)).

The data on pulse width and bilateral ECT are also evolving. In a retrospective study of bilateral ECT in which 65 patients with major depressive disorder received a pulse width of either 0.5 millisecond (brief) or 0.25 millisecond (ultrabrief), the two groups had similar response and remission rates ([Niemantsverdriet et al. 2011](#)). In a prospective randomized trial in which 64 patients received treatment with a course of either bifrontal ultrabrief-pulse (0.3 millisecond) ECT at 1.5 times the seizure threshold or right-unilateral ultrabrief-pulse ECT at 6 times the seizure threshold, the two patient groups showed equivalent response rates, with no changes in cognition in either group ([Sienaert et al. 2010](#)).

However, a randomized trial of 90 depressed patients who were treated with either right-unilateral ECT at 6 times the seizure threshold or bilateral ECT at 2.5 times the seizure threshold, using either a traditional brief pulse (1.5 milliseconds) or an ultrabrief pulse (0.3 millisecond), found that the remission rate with ultrabrief-pulse bilateral ECT was significantly lower than that with brief-pulse bilateral ECT (35% vs. 65%). Ultrabrief- and brief-pulse right-unilateral ECT (remission rates of 73% and 59%, respectively) were as effective as brief-pulse bilateral ECT (65%) but produced fewer cognitive side effects. Of the four treatment groups, ultrabrief-pulse right-unilateral ECT was

associated with the fewest cognitive side effects ([Sackeim et al. 2008](#)).

A recent systematic review concluded that brief-pulse right-unilateral ECT was “slightly” more efficacious than ultrabrief-pulse right-unilateral ECT in treating depression and required fewer treatment sessions but was also associated with more cognitive side effects ([Tor et al. 2015](#)). Other groups have reviewed the data and argued against the use of ultrabrief-pulse right-unilateral ECT, stating that the evidence does not support its selection over brief-pulse right-unilateral ECT ([Spaans et al. 2013a](#)) or over brief-pulse bilateral ECT at 2.5 times the initial seizure threshold ([McCormick et al. 2009](#)) as the first-line treatment. Clinicians considering the use of brief-pulse right-unilateral versus ultrabrief-pulse right-unilateral ECT versus bilateral ECT should take into account clinical factors such as baseline cognitive or neurological status and the severity of psychiatric symptoms, as well as practical issues such as the potential for increased length of the treatment course with brief-pulse treatments ([Galletly et al. 2012, 2014](#)).

The picture with ultrabrief-pulse *bilateral* ECT is less clear, and further research may be needed to determine the relative efficacy of ultrabrief-pulse versus standard brief-pulse bilateral ECT. Some have argued that brief-pulse right-unilateral ECT should be used when a faster speed of response is required, and that brief-pulse bilateral ECT should be used until more research data has accumulated in support of the efficacy of ultrabrief-pulse bilateral ECT ([Loo et al. 2012](#)).

## **Magnitude of the Stimulus Dose**

The consensus regarding the need for convulsive (as opposed to subconvulsive) stimuli and brief-pulse

waveforms would seem to make stimulus dosing in ECT a straightforward process, except for the question of the degree to which the stimulus should exceed the convulsive threshold. For years, ECT practitioners were satisfied that the answer to this question was found in the work of [Ottosson \(1962\)](#), who compared routine ECT with ECT modified by pretreatment with intravenous lidocaine. He found that seizures induced by lidocaine-modified ECT were shorter than those induced by routine ECT and observed an inverse relation between seizure duration and antidepressant effect. From this work, it was widely accepted that stimulus doses producing seizures lasting at least 25 seconds have an antidepressant effect ([American Psychiatric Association 1978](#)).

Initially, ECT was administered with bilateral (typically bitemporal) electrode placement. In [1949](#), [Goldman](#) introduced right-unilateral ECT and placed the stimulating electrodes over the right hemisphere instead of the mesial temporal lobes in an attempt to reduce the direct stimulation of language areas and thereby minimize cognitive side effects. Although right-unilateral ECT was associated with fewer cognitive side effects, most studies showed that bilateral ECT had a marked therapeutic advantage over unilateral ECT for depression ([d'Elia and Raotma 1975](#)).

The clinical wisdom that bilateral ECT was more effective than right-unilateral ECT in treating depression came into question with the work of Sackeim's research group. [Sackeim et al. \(1993\)](#) reported that when the electrical stimulus was just barely above the convulsive threshold, ECT with right-unilateral electrode placement was not efficacious, despite the production of electrographic seizures typically in excess of 25 seconds. However, as the

electrical dose was progressively increased, response rates in right-unilateral ECT improved significantly and approached those of bilateral ECT. In contrast, bilateral ECT was fully efficacious regardless of whether the electrical stimulus was minimally above or 2.5 times the seizure threshold, but excess memory side effects accrued at the higher stimulus dose.

There is a dose-response relationship in right-unilateral ECT only to the extent that the stimulus dose exceeds the convulsive threshold for a given patient; the absolute magnitude of the stimulus dose has no independent influence on this relationship. The efficacy of right-unilateral ECT follows a nearly linear relationship to the degree that the stimulus dose exceeds the seizure threshold, at least through 12 times the seizure threshold ([McCall et al. 2000](#)). This relationship is analogous to the patient-specific dose-response relationship in the pharmacological treatment of depression with tricyclic antidepressants: serum blood levels are more important than the absolute oral dose in determining both efficacy and side effects.

These findings led to the following conclusions:

- With standard brief-pulse stimulation delivered with right-unilateral electrode placement, the stimulus should be substantially above the convulsive threshold in order to ensure the effectiveness of ECT.
- With standard brief-pulse stimulation delivered with bilateral electrode placement, the stimulus should not be excessively above the convulsive threshold in order to avoid undue cognitive side effects.

The convulsive threshold varies by a factor of at least 40 in large patient samples; thus, the mean threshold for a group of patients may not inform the threshold for an individual ([Sackeim et al. 1991](#)). It is clear that the convulsive threshold is related to age, sex, race, choice of stimulating electrode placement, and, perhaps, cranial dimensions ([Chung 2006](#); [Colenda and McCall 1996](#); [Sackeim et al. 1991](#)) and even volume of cerebrospinal fluid estimated on MRI ([van Waarde et al. 2013](#)). Still, these factors predict only a small amount of the variance in the convulsive threshold, and statistical models to predict the convulsive threshold, including age-based dosing approaches, may not yield an accurate estimate of the threshold ([Colenda and McCall 1996](#); [Tiller and Ingram 2006](#)). In addition, a primary factor for an individual patient may be medications that affect the seizure threshold (e.g., benzodiazepines, anticonvulsants), which are difficult to account for in any algorithm estimating the seizure threshold.

## Seizure Morphology

The report of [Sackeim et al. \(1993\)](#) that threshold right-unilateral ECT produced seizures of 25 seconds or longer without antidepressant efficacy cast into doubt the clinical wisdom that the stimulus dose was therapeutic if the electrographic seizure lasted at least 25 seconds. Investigators have sought to find a physiological marker of treatment adequacy to replace seizure duration. The most promising candidate is seizure morphology. [Ottoosson \(1962\)](#) reported that lidocaine changed the shape of ECT seizures, as well as shortening their duration. Lidocaine-modified seizures, in addition to being less efficacious than standard

ECT seizures, were characterized by loss of spike activity and poor postictal suppression.

Seizure morphology varies according to ECT technique. That is, greater seizure intensity correlates with ECT techniques that progress from lower efficacy (with right-unilateral electrode placement and low stimulus intensity) to higher efficacy (with bilateral placement and high stimulus intensity) ([Krystal et al. 1993](#)). Electrode placement and stimulus intensity have independent and additive effects on seizure morphology. Seizures of greater intensity are characterized by higher peak ictal amplitudes, greater stereotypy of the ictal discharge, greater symmetry and coherence between the left and the right cerebral hemispheres, and more profound postictal suppression. Preliminary evidence suggests that greater seizure intensity is predictive of a greater likelihood of response and/or a faster response ([McCall et al. 1993](#); [Nobler et al. 1993](#)).

The natural extension of this reasoning leads to the hope that seizure morphology could guide decisions about stimulus intensity as the course of ECT progresses. For example, if seizure intensity is low in the middle of the treatment course, then the treatment technique should be changed (by switching electrode placement and/or increasing the stimulus intensity) in order to optimize the clinical outcome. Manufacturers of ECT devices now incorporate automated measures of seizure intensity into the ECT chart recorder, and the accompanying owner's manual instructs the practitioner to increase the stimulus intensity if the seizure morphology appears to be degraded. The unstated implication is that degraded seizure morphology is a problem and that increasing the stimulus intensity will fix the problem. This instruction might have

merit if stimulus intensity were the primary determinant of seizure morphology, but other factors, such as age, baseline convulsive threshold, and other intrinsic patient characteristics, likely play an equal role in determining seizure expression ([McCall et al. 1996, 1998](#)). For example, greater seizure durations coupled with greater seizure regularity as shown by electroencephalography at the second ECT session are predictive of a better antidepressive outcome at the conclusion of the ECT course, and this relation is independent of the choice of stimulus electrode placement ([Kimball et al. 2009](#)).

Seizure morphology is little influenced by increasing the stimulus intensity above 2.5 times the seizure threshold. Therefore, it is premature to recommend stimulus dosing on the basis of seizure morphology. The importance of seizure morphology in predicting clinical outcome is far from being understood, and more work is needed if seizure morphology is to become a practical tool for governing ECT technique. Peak heart rate has been proposed as an alternative physiological measure of treatment adequacy, with higher heart rates perhaps indicating better clinical outcomes ([Swartz 2000](#)). Again, this approach has yet to be widely accepted.

## **Integrating the Science of Stimulus Dosing With the Choice of Electrode Placement**

**Estimating the convulsive threshold.** The recent advances in knowledge pertaining to stimulus dosing led to the conclusion that standard brief-pulse right-unilateral ECT should be initiated with a stimulus known to be at least five times the seizure threshold, whereas standard brief-pulse bilateral ECT should be initiated with a stimulus

about 50% above the seizure threshold. Choosing between these two strategies requires consideration of both efficacy and side effects. However, ultrabrief-pulse right-unilateral ECT should be considered for patients who are at risk for cognitive complications from ECT (e.g., Parkinson's disease).

[McCall et al. \(2000\)](#) conducted a randomized comparison of low-dose (1.5 times the seizure threshold) bilateral ECT ( $n=37$ ) and high-dose (8 times the seizure threshold) right-unilateral ECT ( $n=40$ ). Again, depression remission rates were not significantly different for right-unilateral electrode placement (60%) versus bilateral placement (73%), and memory effects were likewise similar. This study can be criticized for lacking sufficient power to detect small but meaningful effects. However, that concern was addressed in a subsequent study ([Sackeim et al. 2009](#)) in which 319 patients who were randomly assigned to receive either standard brief-pulse right-unilateral ECT administered at 6 times the seizure threshold or bilateral ECT administered at 1.5 times the seizure threshold. Although differences between the antidepressant effects of the two treatments were again indistinguishable, the extent of autobiographical memory loss was greater in the bilateral ECT group.

[Kellner et al. \(2010\)](#) conducted a multicenter double-blind, controlled trial in which 230 individuals with major depressive disorder were randomly assigned to one of three electrode placements: bifrontal at 1.5 times the seizure threshold, bitemporal at 1.5 times the seizure threshold, and right unilateral at 6 times the seizure threshold. The investigators found that the three electrode placements were statistically equivalent, with remission rates of 61% with bifrontal, 64% with bitemporal, and 55% with right-unilateral electrode placement. Notably, the patients

treated with bitemporal electrode placement had greater improvement in depression early in the course of treatment. In this study, the investigators used an extensive neuropsychological battery, including measures of autobiographical memory, and found few differences among the three electrode placements on a variety of neuropsychological instruments.

The bulk of the evidence thus suggests that it is desirable to set the stimulus dose as a proportion of the convulsive threshold. The convulsive threshold of each patient should be identified, preferably by measuring convulsive threshold early in the ECT course. The most accurate means of measuring the convulsive threshold for a given patient is empirical observation through use of stimulus “titration” at the initial treatment session—a technique in which an intentionally subconvulsive stimuli is first administered, followed by administration of successively larger stimuli until a seizure is produced. This approach applies to both right-unilateral and bilateral electrode placement.

If ECT practitioners agree with the above reasoning and use this stimulus dosing technique, they should ascertain the convulsive threshold at the first ECT session. However, some ECT researchers have argued against titration of stimulus doses with unilateral ECT and instead have encouraged practitioners to use fixed high doses of unilateral ECT ([Abrams 2002](#)) or fixed moderate doses of bilateral ECT ([Kellner 2001](#)). In fact, an admittedly dated survey of ECT practitioners from 1993 showed that only a minority performed titration of the stimulus dose ([Farah and McCall 1993](#)). The reasons for this are unclear, but possible explanations include concerns that 1) the subconvulsive stimulation inherent in stimulus titration might be medically dangerous, 2) the subconvulsive

stimulation might add to the memory side effects, or 3) the production of a barely suprathreshold seizure with right-unilateral placement would constitute ineffective treatment, thus rendering the first treatment a wasted effort.

Subconvulsive stimulation transiently slows the heart rate, and if a subconvulsive stimulation is administered to patients who have received a  $\beta$ -blocker and no anticholinergic drug, substantial asystole is a risk ([McCall et al. 1994](#)). However, atropine pretreatment eliminates this risk. The possibility of excess acute cognitive side effects with subconvulsive stimuli has been examined and discounted ([Prudic et al. 1994](#)). The possibility of a sluggish antidepressive response when right-unilateral stimulus doses are titrated to a level moderately above the seizure threshold, however, is a reasonable concern that must be weighed against the benefits associated with assessing the seizure threshold to determine the most therapeutic dose for ECT. Of course, an initial titrated suprathreshold bilateral stimulus would be closer to the therapeutic dose (of 1.5-2.5 times the seizure threshold), and the cognitive benefits of ensuring that the dose is not suprathreshold (i.e., >3 times the seizure threshold) are more straightforward.

**Alternatives to estimating the convulsive threshold.** [Abrams \(2002\)](#) suggested that the most efficient method of administering right-unilateral ECT is to use 100% of the maximum device capacity and a pulse width of 0.25-0.50 millisecond and recommended changing to bilateral ECT if the patient does not improve sufficiently. This strategy takes advantage of the cognitive sparing of shorter pulse widths and the efficacy of right-unilateral ECT at high doses. The disadvantages of this strategy are that it

is not adjusted to the individual's seizure threshold and that more cognitive side effects without therapeutic benefit are possible.

Alternatively, twice-weekly bilateral ECT could be initiated using the half-age method ([Abrams 2002](#)). In the half-age method, the age of the patient is divided by 2; the resulting number is the percentage of the device's maximal output with which the patient is first treated (e.g., a 50-year-old would be treated at 25% of the machine's maximal output). The half-age method has been shown to be a reasonable estimate for the therapeutic stimulation in patients receiving bitemporal ECT ([Petrides et al. 2009](#)). As stated earlier, characteristics other than age can influence an individual's seizure threshold, including multiple medications (e.g., benzodiazepines, valproic acid) that the patient may be taking or anesthetic medications such as propofol. For these reasons, this calculation may be problematic.

[Kellner \(2001\)](#) recommended an alternative fixed-dose strategy that involves starting with 75% of the maximal output for right-unilateral ECT and 30%–60% of maximal output for bilateral ECT. Again, these estimates do not provide the individualized dosing that can be achieved with dose titration.

**Choosing an electrode placement and stimulus dose.** As noted earlier, a comparison of the three most commonly used electrode placements found no significant difference in the efficacy or side-effect profiles of right-unilateral at 6 times the seizure threshold, bitemporal at 1.5 times the seizure threshold, or bifrontal electrode placement at 1.5 times the seizure threshold ([Kellner et al. 2010](#)). The absolute response rate, however, favored

bitemporal ECT over the other two electrode placements, and bitemporal ECT was noted to have a faster onset of response. Additionally, bitemporal ECT is associated with reduction of suicidal intent ([Kellner et al. 2005](#)). Therefore, those patients with the most serious complications of major depressive disorder or mania (i.e., active suicidal behavior with intent, catatonia, psychosis) should be considered for brief-pulse bitemporal ECT at 1.5–2.5 times the stimulus threshold. Consideration of high-dose (10 times the seizure threshold) brief-pulse right-unilateral ECT is appropriate given concerns about a particular patient's vulnerability to the cognitive side effects of ECT. No clear guidelines are available for use of right-unilateral ECT in schizophrenia or mania, although some evidence supports bifrontal over bitemporal ECT in schizophrenia ([Phutane et al. 2013](#)) and acute mania ([Hiremani et al. 2008](#)).

In patients who have a treatment-resistant mood or psychotic disorder without an acute danger to themselves, starting with right-unilateral electrode placement should be considered. Again, the decision to start brief-pulse or ultrabrief-pulse ECT can be individualized to the particular patient. The dosing could start with moderately suprathreshold dosing (5–6 times the seizure threshold) and be increased to 10–12 times the seizure threshold without a significant response after 5–6 treatments depending on patient tolerance.

Other situations favoring the use of titrated right-unilateral ECT (with its potential cognition-sparing effects) include treatment of depressed patients with comorbid dementia or other neurological conditions (e.g., Parkinson's disease). The treatment in these patients should minimize even transient memory side effects and may include starting at a very conservative unilateral dose (i.e., five

times the seizure threshold) and increasing the dose as tolerated.

# Electroconvulsive Therapy

## Treatment Procedure

### **Pretreatment Medical Evaluation**

Although no medical condition represents an absolute contraindication for ECT, several clinical conditions may increase the risk of complications from ECT:

- Recent myocardial infarction or unstable cardiac conditions
- Any illness that increases intracranial pressure (e.g., brain tumor)
- Recent cerebral infarction, particularly hemorrhagic infarction
- Aneurysm or vascular malformation
- American Society of Anesthesiology physical status classification level 4 or 5
- Severe pulmonary disease

When treating high-risk patients with ECT, clinicians must evaluate the effects of ECT on cerebral and cardiac physiology and review data from the extant ECT literature to help develop individual risk-benefit ratios ([American Psychiatric Association 2001](#); [Saito 2005](#); [Sundsted et al. 2014](#)). All patients should undergo a thorough medical and neuropsychiatric review before beginning a course of ECT. Particular emphasis should be placed on diseases affecting the CNS and the cardiovascular system. The pre-ECT

evaluation should include a physical examination, a detailed neurological examination, a mental status examination, a medical history, and a review of systems. The patient's mental status should be evaluated before initiation of ECT and monitored closely before administration of ECT at every session thereafter.

## **Electroconvulsive Therapy Administration**

In the United States, the standard anesthetic agent used for ECT is methohexital, a short-acting barbiturate with minimal anticonvulsant effects. Methohexital is given in a dose of approximately 0.75–1.0 mg/kg; one alternative is propofol, given in a dose of approximately 0.75–1.5 mg/kg. Concerns regarding the use of propofol include the fact that it is associated with shorter seizures than methohexital and increases the number of missed seizures (i.e., delivery of an electrical stimulus without induction of a seizure) ([Swaim et al. 2006](#)). However, seizure duration has not been correlated with clinical efficacy, and trials comparing the use of methohexital with the use of propofol have not shown significant differences in the antidepressant efficacy of ECT ([Avramov et al. 1995](#)). Propofol was associated with improved hemodynamic stability and equivalent improvement in depressive symptoms in trials comparing the two anesthetic agents ([Geretsegger et al. 2007](#)).

One strategy to lengthen seizures is to change to the anesthetic etomidate (0.15–0.3 mg/kg), which is associated with significantly longer seizures ([Stadtland et al. 2002](#)), and, in one retrospective naturalistic study, was associated with a significantly shorter treatment course ([Swaim et al. 2006](#)).

Another strategy is to add the ultra-short-acting narcotics remifentanil or alfentanil to methohexital or propofol and

decrease the dose of the methohexital or propofol. These opiates are potentially proconvulsant, suppress the hemodynamic response to the seizure, and can provide anesthesia in lieu of lower doses of methohexital or propofol ([Locala et al. 2005](#); [Vishne et al. 2005](#)).

Immediately after the patient is anesthetized, a muscle relaxant is administered intravenously. Succinylcholine, at doses of 0.75–1.5 mg/kg, is a widely used depolarizing neuromuscular blocking agent. In patients with musculoskeletal disease, a nondepolarizing agent such as rocuronium can be considered. Anticholinergic agents, such as atropine or glycopyrrolate, are used to prevent ECT-induced bradycardia and to minimize airway secretions. Glycopyrrolate does not cross the blood–brain barrier and therefore may be associated with less postictal confusion than atropine in the elderly. When a  $\beta$ -blocker is added to control the ECT-induced rise in blood pressure and heart rate, use of an anticholinergic agent should be considered because the initial response to the ECT stimulus is bradycardia. Atropine (0.4–1.0 mg) or glycopyrrolate (0.2–0.4 mg) can be given either intramuscularly 30 minutes before the ECT treatment or intravenously at the time of treatment.

Regarding dosing of the electrical stimulus, the titration or *method-of-limits* approach involves use of a table with incremental increases in the electrical energy to determine the minimal amount of energy necessary to produce a seizure (i.e., seizure threshold) as monitored by electroencephalography. Typically, a seizure lasting 30–90 seconds occurs during treatment. Seizures lasting longer than 3 minutes should be terminated by administering an anticonvulsant (e.g., a second dose of methohexital or propofol or a short-acting benzodiazepine such as

midazolam). Patients usually are alert and oriented 20–45 minutes after receiving an ECT treatment.

Although anticonvulsant medications should be minimized, if possible, during the ECT course, there is evidence that continuing or starting antidepressant medication during the course of ECT for major depressive disorder may enhance the overall antidepressant response ([Sackeim et al. 2009](#)).

## Management of Electroconvulsive Therapy–Related Side Effects

### Postictal Agitation

Postictal agitation can be a significant problem, with the potential for causing injury to both the patient and the nursing staff caring for the patient ([Augoustides et al. 2002](#)). Postictal agitation is difficult to predict in an individual patient and must be differentiated from status epilepticus. Postictal agitation is characterized by random flailing movements of the patient (in contrast to the rhythmic convulsions of a seizure) and by the fact that the patient does not lose consciousness or manifest the fixed gaze of a patient experiencing a grand mal seizure.

Several strategies exist for treating postictal agitation, and most involve intravenous access. Midazolam or methohexital will often sedate the patient and can be very effective. Additionally, propofol can be used to manage postictal agitation ([Tzabazis et al. 2013](#)). Intravenous haloperidol has been associated with ventricular ectopy ([Greene et al. 2000](#)) and should be used only in patients with cardiac monitors. One of the atypical antipsychotics

with an intramuscular formulation can be effective, with a more benign cardiac profile compared with haloperidol. Dexmedetomidine has been used to treat severe postictal agitation ([Bryson et al. 2013](#); [Cohen and Stewart 2013](#); [O'Brien et al. 2010](#)).

Preventive measures also can be taken. First, the use of a dissolvable atypical antipsychotic medication such as olanzapine at least 10 minutes prior to ECT can be very effective and does not require administration of any additional liquids ([Hermida et al. 2016](#)). Second, current drug use should be reviewed. Lithium has been associated with postictal agitation and prolonged seizures ([el-Mallakh 1988](#); [Jha et al. 1996](#); [Sadananda et al. 2013](#); [Sartorius et al. 2005](#)) and should be discontinued throughout the ECT course or withheld both the night before and the morning of ECT treatments. Use of the anesthetic agent etomidate is also associated with postictal agitation ([Freeman 2009](#)). Additionally, carbidopa has been associated with postictal delirium and should be withheld the morning of ECT treatment ([Nymeyer and Grossberg 1997](#)).

Postictal agitation has been linked to increased serum lactate levels, and some have argued that increasing the succinylcholine dose to decrease ictal muscle activity and subsequent rises in serum lactate levels can help minimize postictal agitation ([Auriacombe et al. 2000](#)). Another strategy therefore may be to increase the succinylcholine dose if any muscle movement occurs during the seizure. However, care should be taken, because another potential cause of postictal agitation is the patient awakening from anesthesia with latent paralysis of the respiratory muscles. Patients describe this experience as very frightening and may question continuing ECT.

## **Interictal Delirium**

Interictal delirium that develops during a course of ECT can persist on days when the patient does not receive a treatment. This side effect is observed primarily in elderly patients and increases in incidence with advancing age ([Figiel et al. 1990](#)). ECT-induced interictal delirium is associated with prolonged hospitalization and an increased risk of falls. Among the elderly, additional risk factors for interictal delirium are 1) Parkinson's disease, 2) Alzheimer's disease, 3) one or more cardiovascular risk factors, and 4) preexisting structural changes in the caudate nucleus observed on brain scans. Patients who develop postictal confusion are likely to have greater retrograde amnesia in the weeks and months after ECT ([Sobin et al. 1995](#)).

The incidence of delirium during a course of ECT can vary dramatically depending on the ECT technique used. As a rule, ECT-induced interictal delirium is a short-lived, reversible side effect if identified early. Once delirium has been identified, ECT treatments should be withheld until it resolves. Subsequent treatments should be administered less frequently and/or at a lower electrical charge.

## **Cardiovascular Side Effects**

ECT is associated with an increased risk of cardiovascular complications in elderly patients who have, or who are at risk for, cardiovascular disease. Studies have found widely varying rates of cardiac complications in elderly patients receiving ECT. The retrospective design of the studies, the lack of continuous cardiovascular monitoring, and the different definitions of what constitutes a cardiac complication probably account for the discrepancies in the

results. Despite these inconsistencies, most studies have found a correlation between cardiac complications and older age. ECT often produces transient systemic hypertension and abrupt transitions in cardiac rate, which can result in myocardial ischemia or arrhythmias. The increased incidence of cardiac complications among elderly patients is probably associated with the increased rate of preexisting cardiac conditions such as hypertension, coronary artery disease, and arrhythmias. On the basis of these observations, several authors have recommended the use of prophylactic cardiac medications to dampen cardiovascular responses during ECT in elderly patients who have (or are at risk for) cardiovascular disease.

Research has documented that labetalol (a medication with both  $\alpha$ - and  $\beta$ -adrenergic-blocking activity), esmolol (a shorter-acting  $\beta$ -blocker) ([Castelli et al. 1995](#); [Shrestha et al. 2007](#)), and nicardipine (a calcium channel blocker) ([Avramov et al. 1998](#); [Zhang et al. 2005](#)) can be safely used to attenuate the cardiac response during ECT.

It is recommended that adequate doses of an anticholinergic medication (intravenous atropine or glycopyrrolate) be used to decrease bradycardia induced by the initial stimulus ([Swartz and Saheba 1989](#)), and anticholinergic medications given before ECT also have been shown to increase cerebral oxygenation and perfusion during the seizure ([Rasmussen et al. 2007](#)). To help prevent ECT-induced hypotension, it is additionally recommended that all patients be adequately hydrated before undergoing ECT. If patients experience significant orthostatic hypotension in the recovery room, labetalol can be switched to the shorter-acting pure  $\beta$ -blocker esmolol.

The anesthetic agent propofol has been shown to have fewer cardiovascular effects than methohexital and can be

used in patients with preexisting cardiac conditions requiring an attenuated hemodynamic response during treatment ([Bailine et al. 2003](#)). As noted earlier, the trade-off is a shortening of the seizure length with the use of propofol.

## **Cognitive Side Effects**

The greatest area of concern with ECT among the lay public, patients, and their families is the potential development of adverse cognitive changes ([Rajagopal et al. 2013](#)). The medical community's concerns about cognitive side effects and the negative images of ECT in the media are important factors in determining the availability of ECT.

The technique by which ECT is administered influences the incidence and severity of cognitive side effects that may develop during a course of ECT. Specifically, electrode placement, the type of electrical waveform, the intensity of the electrical stimulus, and the frequency of ECT sessions all affect cognitive outcomes during ECT. Preexisting structural brain changes (e.g., white matter hyperintensities), medical illness, advancing age, low "cognitive reserve" (assessed in relation to education and occupation), and concomitant administration of certain psychotropic medications also may be risk factors for cognitive side effects from ECT ([McClintock et al. 2014](#); [Oudega et al. 2014](#)).

It is important to recognize that depression itself (especially late-life depression) often causes cognitive deficits, such that successful treatment of depression with ECT often actually improves some aspects of cognition in certain patients. [Hihn et al. \(2006\)](#) showed that prefrontally mediated aspects of cognition, such as attention and immediate encoding, improved during ECT treatment of

depression, whereas long-term memory functions remained impaired. In a review and meta-analysis of 84 studies of patients receiving ECT for depression (total  $N=2,981$ ) in which cognition was assessed with standardized tests, [Semkovska and McLoughlin \(2010\)](#) found that at 15 days post-ECT, several cognitive domains (processing speed, verbal working memory, and executive functioning) showed improvement relative to pre-ECT measures that was presumably attributable to resolution of cognition-impairing psychiatric symptoms.

The memory loss sometimes observed after ECT can be both anterograde and retrograde and has a temporal gradient, being most prominent around the time of treatment and continuing several weeks after the ECT course ([American Psychiatric Association 2001](#); [Sackeim et al. 2000](#)). Delayed recall is more affected than immediate recall, verbal more than visual, and unstructured (e.g., random word lists) more than contextualized (e.g., story recall) ([Semkovska and McLoughlin 2010](#)). In most patients, any anterograde or retrograde memory problems clear quickly after ECT ([Kellner et al. 2010](#); [O'Connor et al. 2001](#)). Episodic or autobiographical memory is particularly vulnerable to the effects of ECT, although autobiographical memory is also impaired by depression itself ([Fraser et al. 2008](#)).

Most evidence indicates that the degree of amnesia and global cognitive impairment incurred acutely during a course of ECT is greater with bitemporal ECT than with unilateral ECT ([Lisanby et al. 2000](#); [Semkovska and McLoughlin 2010](#)), although this conclusion has not been uniformly supported; a randomized trial comparing right-unilateral, bifrontal, and bitemporal ECT found only transient cognitive side effects, with no significant

differences among the three electrode placements ([Kellner et al. 2010](#)). Evidence also suggests that the degree of cognitive side effects increase with the number of treatments administered, the frequency of administration, and stimulus intensity ([Sackeim et al. 2000](#); [Shapira et al. 2000](#)), although not all reports have confirmed these latter points ([Semkovska and McLoughlin 2010](#)).

Some long-term data do not support the notion that these acute differences in cognition in studies of unilateral versus bilateral ECT persist when assessed weeks to months after an ECT course. Although unilateral ECT is associated with fewer memory problems, the cognitive deficits that occur show a dose relationship and increase as the stimulus dose is increased to 8–12 times the seizure threshold ([McCall et al. 2000](#); [Semkovska and McLoughlin 2010](#)). Research comparing bilateral and unilateral ECT has not addressed whether right-unilateral ECT given at a dose of 10–12 times the seizure threshold would cause more cognitive side effects than bilateral ECT given at a dose that is minimally above or 1.5 times the seizure threshold. *Bilateral* ECT in this context generally refers to *bitemporal* electrode placement, but in a meta-analysis of bifrontal ECT for depression, [Dunne and McLoughlin \(2012\)](#) reported less global cognitive impairment with *bifrontal* (vs. *bitemporal*) ECT, a finding on par with the overall global cognitive and amnestic effects of right-unilateral ECT.

The causes of the memory disturbance associated with ECT are multifactorial and likely include the effects of anesthetic drugs, electrode placement, stimulus waveform, generalized seizures, and electrical dose ([Sackeim et al. 2007](#)). Because cognitive effects associated with ECT are perhaps the primary (rational) barrier to more widespread use of a highly effective treatment modality, not surprisingly

researchers have started to explore ways to prevent or lessen these effects. In keeping with the possible cholinergic mechanisms of action of ECT-induced cognitive effects, at least three trials of acetylcholinesterase inhibitors (medications approved for treatment of certain dementias) have been reported in the literature, all small in sample size but all indicating benefit for general cognitive and/or memory-related test scores when the medications were administered during the acute phase of ECT ([Matthews et al. 2013](#); [Prakash et al. 2006](#); [Stryjer et al. 2012](#)). None of the trials reported any serious adverse events with these medications, which is notable in light of theoretical concerns that cholinesterase inhibitors could cause prolonged paralysis when given with the muscle paralytic succinylcholine, commonly used in ECT anesthesia, and concerns that these medications could prolong the bradycardia and/or asystole that may immediately follow the electrical dose administration.

Nonpharmacological efforts to mitigate cognitive side effects also may prove useful. [Choi et al. \(2011\)](#) reported positive early feasibility during ECT of a cognitive remediation intervention adapted from use among persons with mesial temporal lobe epilepsy.

## **Effects on Cerebral Physiology**

Immediately after an ECT treatment, the EEG shows generalized slowing of brain wave activity. This slowing tends to increase and persist longer after successive treatments. After a course of ECT is completed, slow-wave activity gradually decreases, and EEGs show a reversion to baseline activity within 3 months ([Weiner et al. 1986a](#)). Rarely, electroencephalographic abnormalities may persist for more than 3 months. Pre-existing

electroencephalographic abnormalities may increase the risk for developing prolonged abnormalities after ECT, but the clinical significance of these abnormalities is unknown. Findings from functional neuroimaging studies are consistent with post-ECT EEG findings of generalized slowing, especially in prefrontal regions. Evidence from several studies shows decreased cerebral perfusion and metabolism in frontal regions as well as decreased frontal connectivity with subcortical regions after a course of ECT ([Abbott et al. 2014a](#)); some postulate that this is a possible mechanism of action for the antidepressant effects of ECT, that is, quelling the “hyperconnectivity” that has been reported in frontal-subcortical circuits in major depressive disorder ([Bolwig 2014](#)).

## **Does Electroconvulsive Therapy Cause Brain Damage?**

Human autopsy studies of patients who have received ECT have shown no convincing evidence of irreversible brain damage when ECT was administered with current techniques ([Devanand et al. 1994](#); [Scalia et al. 2007](#); [Weiner 1984](#)). These findings are supported by a brain MRI study in which no significant structural brain changes were found immediately or 6 months after the completion of ECT ([Coffey et al. 1991](#)). In a study of six depressed patients, cerebrospinal fluid markers of neuronal/glial degeneration (tau protein, neurofilament, and S-100 beta protein) were measured before and after a successful course of ECT and showed no biochemical evidence of neuronal/glial damage or blood-brain barrier dysfunction ([Zachrisson et al. 2000](#)). In fact, emerging evidence supports quite the opposite of these commonly held beliefs and fears among the public.

ECS in animal studies has been associated with increased neurogenesis, synaptogenesis, angiogenesis, and gliogenesis, particularly in the hippocampus ([Bouckaert et al. 2014](#)). Human structural neuroimaging studies have identified increased gray matter volume and increased hippocampal volume following ECT, and magnetic resonance spectroscopy studies have reported increased chemical markers of neurogenesis ([Abbott et al. 2014b](#)).

## Prophylactic Somatic Treatment After Acute Response to Electroconvulsive Therapy

Although the short-term therapeutic benefits of ECT for depression have been clearly established, the 6-month relapse rate after ECT remains high ([Bourgon and Kellner 2000](#)). [Sackeim et al. \(1990\)](#) followed 58 patients for 1 year after ECT and found a relapse rate of 64% in patients with major depressive disorder (with and without psychotic features) in whom an adequate pre-ECT medication trial had failed. In contrast, the relapse rate in patients who had not received an adequate pre-ECT antidepressant trial was only 32%. Other clinical and demographic factors, including the presence of delusions, were not significant in predicting relapse. The adequacy of the post-ECT maintenance medication did not correlate with relapse rates. However, maintenance medications post-ECT were not standardized, and the evaluation of the pre-ECT medication trial was retrospective. The conclusion of this study is intuitively appealing: patients whose symptoms do not respond to antidepressant medication before ECT are those most likely

to relapse with maintenance medication after ECT. With relapse occurring in almost two-thirds of such patients within 1 year after ECT, the relapse rate is alarmingly high.

In a prospective randomized, double-blind trial, [Sackeim et al. \(2001a\)](#) compared three maintenance strategies: placebo, nortriptyline (target steady-state level=75–125 ng/mL), and nortriptyline plus lithium (target lithium steady-state level=0.5–0.9 mEq/L). Over the 24-week trial, the depression relapse rate was 84% with placebo, 60% with nortriptyline, and 39% with nortriptyline plus lithium, indicating a statistically significant advantage for combination therapy. In another prospective study, [Shapira et al. \(1995\)](#) found that patients who responded to an acute course of ECT and subsequently received maintenance therapy with lithium for 6 months had a relapse rate of only 36%. Of the 22 patients, the 8 who relapsed did so within the first 13 weeks. Clinical factors associated with relapse included a shorter duration of the index depressive episode, an additional depressive episode in the 12 months prior to ECT, and, again, failure of an adequate trial of antidepressant therapy before the ECT course.

The high relapse rates of depression in patients receiving antidepressant medications after a successful course of ECT have led clinicians to use alternative therapies, such as continuation and maintenance ECT, in patients who are at high risk for recurrence of their mood disorder. *Continuation ECT* is defined as ECT for up to 6 months after the acute ECT course (i.e., aimed at relapse prevention). Continuation ECT is differentiated from *maintenance ECT*, which is defined as ECT that continues for more than 6 months after the initial course (i.e., aimed at recurrence prevention).

The term *prophylactic ECT* is used to refer to any ECT treatments given as continuation or maintenance therapy. According to clinical guidelines, candidates for prophylactic ECT include patients who have recurring affective episodes that are responsive to ECT and/or who are resistant to, intolerant of, or noncompliant with antidepressant medications ([American Psychiatric Association 2001](#)). The debate over appropriate prophylactic treatment for patients who have acutely responded to ECT has focused on the clinical decision to either continue therapy with antidepressant medications or initiate maintenance ECT. The pivotal study in understanding this debate compared continuation psychopharmacology with nortriptyline and lithium with continuation ECT in 201 patients whose depression had remitted with an acute course of bilateral ECT ([Kellner et al. 2006](#)). No statistical difference was seen in relapse rates for the two groups, and more than half of the patients in each group relapsed. This study reported high relapse rates after an acute course of ECT, even with an aggressive pharmacological approach, but the relapse rates in both groups were significantly lower than relapse rates in patients in other studies who received placebo.

---

## **Other Neuromodulation Therapies**

---

Subconvulsive Stimulation  
Therapies: rTMS and VNS

To date, two types of subconvulsive therapies have received device approval from the U.S. Food and Drug Administration (FDA) for use in the treatment of depression: rTMS and vagus nerve stimulation (VNS).

## **Repetitive Transcranial Magnetic Stimulation**

The efficacy of TMS therapy is now well established and calls into question the axiom that subconvulsive stimuli cannot be therapeutic. TMS transiently entrains cortical oscillatory rhythms detected with surface EEG electrodes ([Brignani et al. 2008](#); [Johnson et al. 2010](#)). Interleaved imaging with TMS applied to prefrontal cortex shows that it immediately induces activation in subcortical limbic regions as well as cortical areas directly beneath the coil ([Li et al. 2004](#)). Other studies have found TMS-associated production of BDNF and cellular proliferation in the hippocampus ([Wang et al. 2014](#)), normalization of medial prefrontal-medial parietal default network connectivity ([Liston et al. 2014](#)), and modulation of oscillatory rhythms ([Ding et al. 2014](#); [Fuggetta and Noh 2013](#)). However, similar to many other antidepressant treatments, the putative mechanism of therapeutic action of TMS is not known.

At the time of this chapter's publication, five devices were cleared by the FDA for TMS treatment of major depressive disorder. Four of these (Deep TMS by Brainsway, Rapid2 by Magstim, MagVita by MagVenture, and NeuroSoft TMS) were cleared by the FDA under a regulatory pathway that required the manufacturer to document substantial equivalence with predicate TMS devices in adult patients who had failed to receive satisfactory improvement from prior antidepressant medication in the current episode.

Neuronetics reported a significant effect for TMS treatment in a double-blind, sham-controlled multisite trial in 301 medication-free depressed patients ([O'Reardon et al. 2007](#)), albeit with a modest remission rate of 17% in active treatment compared with 8% in sham. In October 2008, the FDA approved NeuroStar TMS for patients with depression whose symptoms had failed to respond to antidepressant medication trials. In a study using the Neuronetics TMS devices and the same stimulation parameters, but with funding from the National Institute of Mental Health, [George et al. \(2010\)](#) replicated the positive results reported by the industry-sponsored trial. This trial confirmed the superiority of active TMS relative to sham TMS for symptoms of major depressive disorder in a blinded controlled trial involving 199 antidepressant drug-free patients with a remission rate of 14% in active treatment compared with 5% in sham. Despite these low remission rates in the sham-controlled studies, a multisite observational study conducted after FDA clearance in 307 outpatients with major depressive disorder found a 56.4% response rate and a 28.7% remission rate as assessed on the Patient Health Questionnaire ([Carpenter et al. 2012](#)). Also encouraging were the follow-up data on the 257 patients who completed a course of rTMS in this study ([Dunner et al. 2014](#)). Overall, the proportion of patients who had achieved remission at the conclusion of acute treatment was similar at 1-year follow-up, with about one-third receiving additional TMS.

The Brainsway randomized controlled trial ([Levkovitz et al. 2015](#)) in 212 patients with pharmacoresistant major depressive disorder also showed significantly higher remission rates for active TMS compared with sham (32.6% vs. 14.6%). These results were used to obtain regulatory

clearance for the Deep TMS device in 2013. FDA approvals for the Magstim, MagVenture, and NeuroSoft devices were granted on the basis of coils and stimulators that were similar to those in earlier TMS systems.

## **Vagus Nerve Stimulation**

Originally approved by the FDA for use in patients with treatment-resistant epilepsy, VNS therapy exerts its effect by applying intermittent subconvulsive electrical stimulation to the left vagus nerve. The left vagus nerve has autonomic connections to limbic and cortical areas that are known to be involved in mood regulation ([George et al. 2000](#); [Nemeroff et al. 2006](#)), and as previously discussed, a putative effect of ECT is to act as an anticonvulsant ([Sackeim 1999](#)) (see “Anticonvulsant Hypothesis” subsection earlier in this chapter). Studies of the effect of VNS on mood regulation in a small sample of patients with epilepsy reported a trend toward mood improvements ([Elger et al. 2000](#)) or showed a positive effect on mood that was no different from that seen in a group of epilepsy patients taking anticonvulsant medications alone ([Harden et al. 2000](#)). However, a 10-week open pilot study of 60 depressed nonepileptic patients showed a response rate of 31% and a remission rate of 15% ([Rush et al. 2000](#); [Sackeim et al. 2001b](#)), and the initial treatment response continued over the following 2 years ([Nahas et al. 2005](#)).

These pilot data served as the basis for a larger multicenter trial in 222 patients ([Rush et al. 2005a](#)). The study design included a 2-week single-blind recovery period after implantation (during which patients received no stimulation), followed by 10 weeks of masked active VNS treatment or sham treatment. At 10 weeks, response rates were 15% for the active-treatment group ( $n=112$ ) and 10%

for the sham-treatment group ( $n=110$ ) ( $P=0.251$ ). Although this study did not yield definitive evidence of short-term efficacy for adjunctive VNS in patients with treatment-resistant depression, the patients were subsequently followed for 1 year in a naturalistic study in which they received VNS and antidepressant treatments, both of which could be adjusted ([Rush et al. 2005b](#)). These flexible conditions should be kept in mind when considering the reported 1-year results—a response rate of 27% (55/202) and a remission rate of 16% (32/202). In another 1-year study, VNS patients showed significant improvement in comparison with a matched control group of patients with similar treatment-resistant depression who were receiving only medication ([George et al. 2005](#)). The FDA considered these data and approved the Cyberonics VNS Therapy System in 2005 for adjunctive long-term treatment of chronic or recurrent depression in adults who have not had adequate response to four or more adequate antidepressant treatments.

## Comparisons of VNS and TMS With Electroconvulsive Therapy

Studies directly comparing the antidepressant efficacy of TMS and ECT are limited. A comparative effectiveness review prepared for the U.S. Agency for Healthcare Research and Quality (AHRQ) included four trials comparing ECT with rTMS ([Gaynes et al. 2011](#)). Three trials rated “fair” in quality (defined as “susceptible to some bias but probably not sufficient to invalidate its results”) did not find a difference in response or remission rates between TMS and ECT ([Grunhaus et al. 2003](#); [Hansen et al.](#)

2011; Rosa et al. 2006). One study rated as “good” in quality (defined as “has the least bias, and results are considered to be valid”) was a multicenter trial comparing an average of 6 bilateral ECT sessions with a fixed course of 15 high-frequency TMS sessions in a mixed population of patients with unipolar and bipolar depression (McLoughlin et al. 2007). The investigators in this study found a 59% remission rate for patients in the ECT group, which was significantly higher than the rTMS remission rate (17%), and determined that ECT was more cost-effective. In the AHRQ analysis, Gaynes et al. (2011) concluded that they could not ascertain any true pattern of superiority between ECT and TMS because of the limited number of studies and the fact that the study methods and study populations were so heterogeneous.

Nine published trials have compared ECT with high-frequency TMS applied to the left prefrontal cortex, and in one trial, TMS was applied to the right side (see review by Janicak and Carpenter 2014). Although several reviews have not identified superiority of one treatment over the other for patients with pharmacoresistant depression, subsequent authors of meta-analyses have suggested that ECT may be more efficacious for patients with treatment-resistant and psychotic depression (Berlim et al. 2013; Ren et al. 2014). TMS is currently indicated only for nonpsychotic outpatients with unipolar depression, reflecting the fact that regulatory trial samples excluded those who had bipolar disorder, were acutely suicidal or psychotic, or required hospitalization. Because the FDA “label” and insurance eligibility specify these exclusions, the types of patients who receive TMS in many clinical practice settings are fundamentally different from those who receive ECT (i.e., in many psychiatric care settings, ECT is initiated

during an episode of hospitalization). Patients who are imminently suicidal, catatonic, or failing to thrive as a result of severe depression are not candidates for TMS or any other neuromodulatory treatment currently available, except ECT.

No efficacy studies have compared VNS with ECT. Although transcutaneous VNS devices may offer a noninvasive future option ([Fang et al. 2016](#)), the currently approved VNS therapy device requires surgery for initial implantation, for replacement of depleted batteries in the pulse generator, and for removal of device components in the face of clinical nonresponse or emergence of a contraindication associated with nonremovable ferromagnetic metal. VNS also may have a longer latency to onset of positive response than ECT, with some VNS patients requiring several months—and multiple changes in stimulation parameters—to show response. Patients whose symptoms do not respond or worsen while receiving VNS may be unable to transition to alternative noninvasive neuromodulation treatments that involve delivery of strong magnetic or electrical fields because of risk of injury from potential induction or conduction of current through VNS device components.

## Investigational Neuromodulation Techniques

Several neuromodulation procedures are being investigated in mood disorders. These procedures exert their therapeutic effect by depolarizing neurons and initiating action potentials or modulating cell firing rates

resulting in the induction of neuroplastic changes in neural networks ([Rossini et al. 2015](#)).

## **Magnetic Seizure Therapy and Focal Electrically Administered Seizure Therapy**

Convulsive magnetic seizure therapy (MST) and focal electrically administered seizure therapy (FEAST) are designed to induce seizures with more focal stimulation of the cortex than with ECT and potentially produce a therapeutic seizure with fewer cognitive side effects.

MST uses high-intensity, rapidly fluxed magnetic fields to produce seizure-inducing electrical currents in the brain. MST delivers a very-high-frequency stimulus (e.g., 100 Hz) that results in an electrical field that is more focal and superficial than that with ECT ([Deng et al. 2011](#)). The stimulus has less of a direct effect on the mesial temporal structures (e.g., hippocampus) and theoretically is associated with fewer cognitive side effects than is ECT. To date, only small nonrandomized trials have evaluated the efficacy of MST. MST was shown to be equivalent to ECT in one study ([Kayser et al. 2011](#)), although another study showed a less consistent response ([Fitzgerald et al. 2013](#)). Cognitive safety has been either equivalent to ([Fitzgerald et al. 2013](#); [Kayser et al. 2011](#)) or better than ECT ([Lisanby et al. 2003](#); [Polster et al. 2015](#)).

The electrical stimulus used in FEAST technology induces more focal seizures in the prefrontal cortex by changing the ECT bipolar pulse to a monopolar pulse by using a smaller anode (positive electrode) placed frontally and a larger cathode (negative electrode) on the vertex ([Nahas et al. 2013](#)). A single photon emission computed tomography scan of a patient receiving FEAST showed increases in

regional cerebral blood flow that were limited to the right prefrontal cortex, with postictal changes generalized bilaterally ([Chahine et al. 2014](#)). A small open-label study confirmed an antidepressant effect ([Nahas et al. 2013](#)), but future studies are needed to support the efficacy of this novel approach to convulsive therapy.

## **Transcranial Direct Current Stimulation**

Several other neuromodulation modalities are subconvulsive, including transcranial direct current stimulation (tDCS) and transcranial alternating current stimulation, cranial electrotherapy stimulation, low field magnetic stimulation with or without synchronization of pulses to intrinsic brain rhythms, DBS, and external trigeminal nerve stimulation; these hold promise both for the treatment of mood disorders and for elucidating the underlying biology of depression. We focus on two representative subconvulsive neuromodulation techniques under investigation: tDCS and DBS.

tDCS uses a constant low current (1-2 mA) applied continuously for 10-20 minutes through anodal and cathodal electrodes applied to the scalp with the goal of modulating the spontaneous firing rates of cells. tDCS differs from TMS in that it does not directly initiate action potentials and instead causes small changes in the membranes of cell bodies to modulate spontaneous firing rates and functional connectivity ([Polanía et al. 2011, 2012](#); [Rossini et al. 2015](#)). Two meta-analyses have found that tDCS was associated with moderate efficacy in major depressive disorder with no significant side effects ([Kalu et al. 2012](#); [Shiozawa et al. 2014](#)).

## **Deep Brain Stimulation**

Perhaps the neuromodulation procedure that has generated the most interest in both the scientific community and the lay public is DBS. DBS requires surgical implantation of a device system with intracranial placement of bilateral electrodes whose tips are precisely inserted into the targeted brain region. Extension wires tunneled from the electrodes are connected with bilateral pulse generators, similar to those used in VNS, implanted subcutaneously in the chest wall. Open-label studies showed initial promise for DBS as a therapeutic subconvulsive stimulus for depression ([Holtzheimer et al. 2012](#); [Malone et al. 2009](#); [Mayberg et al. 2005](#); [Schlaepfer et al. 2013](#)). However, when DBS was subsequently tested with stimulation at two different anatomical targets in large randomized, sham-controlled trials, antidepressant efficacy could not be confirmed. Both the Medtronic RECLAIM trial, which evaluated DBS to ventral capsule/ventral striatum ([Dougherty et al. 2015](#)), and the St. Jude Medical BROADEN trial, which investigated DBS targeted at subgenual cingulate cortex ([Morishita et al. 2014](#)), were halted because of a lack of separation between active and sham groups.

[Morishita et al. \(2014\)](#) performed a systematic review of 22 published reports of DBS trials for depression targeting six different anatomical sites: nucleus accumbens, ventral striatum/ventral capsule, subgenual cingulate cortex, lateral habenula, inferior thalamic nucleus, and medial forebrain bundle. They found that response rates across 22 trials were consistently reported in the range of 40%–70%, but only 3 of the trials were controlled, and results from the 2 industry-sponsored trials were not included, so they concluded that DBS for depression remains investigational.

The most recently reported clinical DBS data include two randomized discontinuation trials. The first trial was a double-blind crossover study in five previously implanted patients with treatment-resistant depression that had remitted with chronic DBS in the subcallosal cingulate gyrus ([Puigdemont et al. 2015](#)). A significant effect of DBS was seen, with more patients remaining in remission during the 3 months when active stimulation was continued compared with the 3 months when stimulation was off with sham programming procedures. The second trial was an open-label study in which DBS was delivered to the anterior limb of the internal capsule during a parameter optimization phase that lasted up to 1 year in a relatively large sample ( $N=25$ ) of depressed patients, yielding a 40% response rate ([Bergfeld et al. 2016](#)). Sixteen of the subjects subsequently entered a randomized crossover phase; the group had significantly higher depression severity scores during sham DBS than during active stimulation.

The efficacy of DBS therapy has not been compared with that of ECT, and the safety of ECT for patients who have already been implanted with a DBS system has not been established. The main risk is induction of electrical currents by ECT, leading to damage of the implanted DBS components, interference with intended stimulation, undesirable stimulation effects, or neurological injury. Although DBS has not received regulatory approval to treat depression, the Medtronic Reclaim DBS device was granted U.S. FDA humanitarian device exemption status for the treatment of chronic, severe, treatment-resistant obsessive-compulsive disorder as an alternative to anterior capsulotomy. Several DBS devices are also approved for Parkinson's disease and essential tremor. Some published articles highlight ethical considerations for DBS in the

treatment of psychiatric disorders ([Saleh and Fontaine 2015](#); [Unterrainer and Oduncu 2015](#)). In light of the potentially significant risks associated with surgical implantation of DBS electrodes and the lack of biomarkers to guide optimal targets for stimulation, incorporation of this treatment modality into standard psychiatric practice awaits further efficacy and safety data from large controlled trials.

---

## Conclusion

---

More than 80 years have passed since ECT was first used in the treatment of psychiatric disorders. The scientific evidence for the safety and efficacy of ECT has grown exponentially, and no available medical treatment is as effective in treating debilitating, life-threatening symptoms including treatment-resistant depression, mania, catatonia, and psychosis. Other neuromodulation techniques, both convulsive and subconvulsive, hold promise for elucidating neuroanatomical pathways and expanding the range of available treatments for mood disorders. Further research is needed to determine which biomarkers and patient variables are associated with response to each of these treatments. However, for patients with severe treatment-resistant mood disorders and schizophrenia, ECT remains the gold standard.

## **PART III**

# Psychopharmacological Treatment

# CHAPTER 46

## Treatment of Depression

William V. Bobo, M.D., M.P.H.

Richard C. Shelton, M.D.

Major depressive disorder (MDD) affects more than 350 million people worldwide ([World Health Organization 2012](#)), making it one of the most prevalent illnesses in all of medicine. MDD is characterized by pronounced changes in mood (persisting depressed mood or anhedonia) coupled with distinct psychological (feelings of worthlessness or excessive guilt, difficulties maintaining concentration) and neurovegetative (sleep and/or appetite disturbance, fatigue or loss of energy and drive) changes and, all too often, suicidal thinking and behavior ([American Psychiatric Association 2013](#)). For many patients with MDD, the illness course is episodic, whereas others may experience more prolonged episodes that persist for years ([Coryell et al. 1994](#); [Eaton et al. 2008](#); [Stegenga et al. 2012](#)).

The adverse effects of MDD on quality of life and functioning are staggering. Pooled estimates of global disease burden ranked MDD as the second leading cause of years of life lived with a disability in 2010, accounting for 8.2% of global years of life lived with a disability ([Ferrari et al. 2013](#)). Even milder but more chronic and persisting forms of unipolar depression, such as persistent depressive disorder (dysthymia) (formerly known as dysthymic disorder), are among the leading causes of disability in the United States ([Murray et al. 2013](#)). The goal of treatment of all forms of

depression is to return patients to an asymptomatic state (remission), restore “normal” psychosocial functioning, prevent relapses of depression once patients are well, and minimize adverse effects of treatment ([Davidson 2010](#)). Thus, the treatment of patients with MDD and other depressive disorders requires aggressive and varied therapies that may need to continue for years, if not indefinitely.

---

## Epidemiology

---

### Prevalence of Depressive Disorders

MDD is one of the most common medical disorders affecting adults worldwide ([Lopez and Murray 1998](#); [World Health Organization 2012](#)). In the United States, the lifetime prevalence of MDD is 9% for men and 17% for women ([Hasin et al. 2005](#)), whereas the lifetime prevalence of dysthymia is 4% for men and 8% for women ([Kessler et al. 1994](#)). The lifetime prevalence of minor depression, a type of depression with milder symptoms than MDD, is 10% for individuals between the ages of 15 and 54 years ([Kessler et al. 1997](#)). For persons 65 years and older, the 1-month point prevalence of minor depression is 13%, which is twice the prevalence of MDD for this age group ([Judd and Akiskal 2002](#); [McCusker et al. 2005](#)). The lifetime prevalence of subsyndromal depression is 11.8% for the general population ([Goldney et al. 2004](#); [Judd et al. 1994](#)).

### Risk Factors for Depressive Disorders

Risk factors for MDD and other depressive disorders are numerous and include demographic, biological (genetic), and psychosocial (environmental) factors. Risk factors with the strongest body of evidence include female sex, age, a family history of a mood disorder, a history of psychological trauma or childhood adversity, and comorbid medical and psychiatric conditions.

A significant body of evidence indicates that sex is an important risk factor for the development of MDD. Prior to puberty, the prevalence of depression is equal in boys and girls. However, beginning with puberty, women demonstrate a twofold increase in the prevalence of MDD ([Burt and Stein 2002](#); [Hasin et al. 2005](#); [Kessler et al. 1994](#); [Weissman and Klerman 1977](#)). This trend is seen across countries and ethnic groups ([Joyce et al. 1990](#); [Lee et al. 1990, 2009](#); [Slone et al. 2006](#); [Weissman et al. 1996](#)). However, sex does not appear to affect rates of illness recurrence among people with MDD ([Kessler et al. 1993](#)). The lifetime prevalence rate of persistent depressive disorder (dysthymia) is also higher in women than in men ([Alonso et al. 2004](#); [Chiu 2004](#); [Falk et al. 2008](#); [Lee et al. 1990](#); [Weissman et al. 1988](#)).

Age is another risk factor in the development of depressive disorders; the onset of MDD can occur at any age, but onset appears to increase dramatically beginning in adolescence (12–16 years) and continuing through the age of about 44 years ([Hasin et al. 2005](#)). Whereas the mean age at onset has been reported to be 30 years, the mean age at the start of treatment is 33.5 years, a 3-year span reflecting the amount of time that depression remains undiagnosed or untreated. Early age at MDD onset (i.e., onset during childhood or adolescence) appears to be associated with more severe and recurrent forms of illness, more lifetime suicide attempts, and a greater illness burden ([Zisook et al. 2007](#)). In elderly individuals, risk factors for depression include female sex, low socioeconomic status, recent bereavement, prior depression, medical comorbidity, disability, cognitive deterioration, and vascular disease ([Helmer et al. 2004](#)).

A family history of psychiatric illness, particularly MDD, is among the most profound risk factors for the development of a major depressive episode ([Reinherz et al. 2003](#); [Sullivan et al. 2000](#)). Compared with the general population, first-degree relatives of patients with MDD have two to four times the risk of developing MDD ([Gershon et al. 1982](#); [Weissman et al. 1984](#)). Estimated heritability rates of up to 46% for MDD based on data from twin studies strengthen the notion of a strong genetic basis for MDD risk ([Kendler et al. 1993](#)).

Prolonged exposure to severe traumatic events in childhood and adolescence has also been linked to the development of depressive episodes later in life ([Alloy et al. 2006](#); [Hammen 2005](#); [Hosang et al. 2010](#)). Trauma such as sexual abuse or the loss of a parent that occurs at a critical developmental period can result in permanent alteration of stress-related neuroendocrine systems (especially the hypothalamic-pituitary-adrenal [HPA] axis) and immune/inflammatory markers ([Ehlert 2013](#)). It is recognized that individuals with depression, particularly those exposed to early trauma, have altered stress and pro-inflammatory responses ([Danese et al. 2008](#); [Gillespie and Nemeroff 2005](#); [Heim et al. 2000, 2008](#); [Nemeroff and Vale 2005](#)).

Other clinical and demographic variables have been linked to an increased risk of developing depressive disorders. These include stressful life events such as the death of a loved one, divorce, or job loss ([Kendler et al. 1999](#)). Certain personality characteristics may also predispose an individual to developing a mood disorder. Individuals who score higher on measures of neuroticism, interpersonal dependency, or external locus of control may be vulnerable to stressful life events precipitating a major depressive episode ([Hirschfeld et al. 1983](#); [Paykel et al. 1996](#)). Investigations suggesting that some cultural groups may be at increased risk of mood disorders (Native Americans) or may have greater inherent resilience (Asian and Hispanic groups) are an area of continued interest ([Hasin et al. 2005](#)), as are potential epigenetic mediators of the effect of stressful life events (including childhood trauma) on the risk of MDD across generations ([Franklin et al. 2010](#); [Sun et al. 2013](#)).

Many medical illnesses are comorbid with MDD ([Table 46-1](#)). Cancer, AIDS, respiratory disease, cardiovascular disease, Parkinson's disease, and stroke are associated with an increased risk for depression ([Katon 2003](#)). MDD is associated with poorer outcomes in medically ill persons. For example, in patients with coronary heart disease and heart failure, depression is associated with a higher risk of rehospitalization and mortality ([Rutledge et al. 2006](#); [van Melle et al. 2004](#)). The clinical course and level of functioning are poorer in patients with MDD and co-occurring medical conditions ([Katon and Schulberg 1992](#); [Keitner et al. 1991](#)).

**TABLE 46-1. Medical conditions often comorbid with major depressive disorder**

<b>Infectious conditions</b>	<b>Metabolic conditions</b>	<b>Neurological conditions</b>	<b>General medical conditions</b>
Encephalitis	Addison's disease	Brain tumor	Alcohol or sedative withdrawal
Hepatitis	Cushing's disease	Dementia, cortical	Arthritis
HIV/AIDS	Diabetes	Dementia, subcortical	Cancer
Influenza	Hyponatremia	Huntington's disease	Cardiovascular disease
Meningitis	Nutritional deficiencies	Migraine headaches	Chronic pain syndromes
Mononucleosis	Pituitary dysfunction	Multiple sclerosis	Cocaine or stimulant withdrawal
Pneumonia	Renal disease	Parkinson's disease	Connective tissue diseases
Postviral syndrome	Thyroid disease	Poststroke syndrome	Fibromyalgia
Syphilis		Seizure disorders	Heavy metal poisoning
Tuberculosis		Traumatic brain injury	Irritable bowel syndrome
Urinary tract infection			Liver failure
			Menopause
			Myocardial infarction
			Premenstrual dysphoric disorder
			Pulmonary disease

*Note.* AIDS=acquired immunodeficiency syndrome; HIV=human immunodeficiency virus.

<b>Infectious conditions</b>	<b>Metabolic conditions</b>	<b>Neurological conditions</b>	<b>General medical conditions</b>
			Selenium toxicity
			Sleep disturbance

*Note.* AIDS=acquired immunodeficiency syndrome; HIV=human immunodeficiency virus.

MDD is also highly comorbid with other psychiatric disorders. In primary care settings, more than 75% of patients with diagnosed depression also have an anxiety disorder (Olfson et al. 1997). Patients with depression and anxiety have more chronic and severe illness, greater occupational and psychosocial impairment, and (when the comorbidity is unrecognized) higher rates of psychiatric hospitalization and suicide attempt (Hirschfeld 2001; Sareen et al. 2005). In acknowledgment of the high comorbidity of anxiety disorders with MDD, DSM-5 includes a specifier—“with anxious distress”—that can be added to a major depressive episode diagnosis if at least two of the following symptoms are present during the majority of the episode: feeling keyed up or tense, feeling unusually restless, difficulty concentrating because of worry, fear that something awful may happen, and feeling that one might lose control of oneself (American Psychiatric Association 2013). High anxiety in the context of MDD is associated with lower rates of response to initial treatment with an antidepressant (Fava et al. 2008).

Substance use disorders are also highly comorbid with depressive disorders. The reported prevalence of depressive disorders in patients with alcohol use disorder is 15%–67%; for patients with cocaine use disorder, the prevalence is 33%–53%, and for patients with opioid use disorder, the lifetime rate of mood disorders ranges from 16% to 75% (Davis et al. 2005; Rapaport et al. 1993; Zimmerman et al. 2002). As is the case with comorbid anxiety, co-occurring substance use disorders are associated with worse long-term outcomes and illness course in individuals with MDD (Davis et al. 2005), including higher rates of suicide (Sher et al. 2005).

Remission from substance use has been shown to reduce the risk of depression ([Agosti and Levin 2006](#)).

In summary, there are several biological and nonbiological factors that can increase the risk of developing a depressive disorder.

## Disability and Costs Associated With Depressive Disorders

MDD is associated with significant disease burden, exceeding that of cerebrovascular disease, cancer, and numerous other chronic medical illnesses ([Wells et al. 1989](#); [World Health Organization 2004](#)). It is the leading cause of years lived with disability worldwide for young adults ([Lopez et al. 2006](#)) and is predicted to become the second leading cause of disability (behind HIV/AIDS) worldwide by the year 2030 ([Mathers and Loncar 2006](#)). It is estimated that the economic burden of adults with MDD in the U.S. is \$210.5 billion, 45% of which is attributable to direct costs, 50% to workplace costs, and 5% to suicide-related costs ([Greenberg et al. 2015](#)).

The most severe outcome for persons with depressive disorders is death by suicide. Suicide is the tenth leading cause of death in the United States across all age groups (~37,000 known suicides were identified in the 2009 census), the second leading cause of death for individuals between the ages of 25 and 34 years, and the third leading cause of death for young people between the ages of 15 and 24 years ([Kochanek et al. 2012](#)). Data from the 2013 National Survey on Drug Use and Health showed that among an estimated 15.7 million adults with a major depressive episode in 2013, 4.4 million (28%) had serious thoughts of suicide ([Substance Abuse and Mental Health Services Administration 2014](#)). Individuals with unipolar depressive illnesses including MDD have 20 times the risk of dying by suicide compared with the general population ([American Association of Suicidology 2009](#); [Harris and Barraclough 1997](#)). Among depressed individuals, suicide risk is highest among males and among persons with past suicide attempts, with more severe depression, with hopelessness, and with comorbid substance use, anxiety, and personality disorders ([Hawton et al. 2013](#)).

In summary, depressive disorders in general and MDD in particular are costly and are associated with adverse effects on functioning, including disability that is as severe as—or more severe than—disability associated with most chronic medical illnesses. Depressive disorders are the diagnoses most commonly associated with suicide. Suicidal ideation with intent and a plan is a medical emergency that merits the same type of acute response that a physician would give to a myocardial infarction or stroke.

---

## Neurobiology of Depression

---

Current evidence suggests that there is no single, unifying etiopathophysiology for MDD ([Kupfer et al. 2012](#)). However, certain neurobiological alterations have been consistently observed in animal models of MDD and in human patients, many of which are modifiable through antidepressant or other biological treatments for MDD. These neurobiological markers of MDD are discussed below.

### Dysregulation of Neurotransmitter Functioning

For several decades, drug development and biological treatment models for MDD were based primarily on the hypothesis that abnormalities in monoamine neurotransmitter signaling caused the psychological and neurovegetative signs and symptoms of the disorder ([Owens 2004](#)). Indeed, all known orally administered antidepressant medications interact with monoamine transporters or receptors or with enzymes responsible for their degradation ([Li et al. 2012](#)). Although this hypothesis has added profoundly to our understanding of the pathophysiology of MDD and the mechanisms of antidepressive treatment response, it alone cannot explain the wide variation in phenotypic presentation across large numbers of affected patients, nor can it explain the tremendous interindividual variability in clinical response to antidepressants ([Hindmarch 2001](#)).

As our understanding of the mechanism of action of antidepressant therapies has grown, more attention has been given to other neurotransmitter systems. Converging evidence from postmortem genetic in vivo neuroimaging studies has implicated glutamate abnormalities in the pathophysiology of mood disorders, including MDD ([Duman 2014](#); [Sanacora et al. 2012](#)). Moreover, pharmacotherapies that target glutamatergic *N*-methyl-D-aspartate (NMDA) receptors have shown considerable promise as putative antidepressants. For example, subanesthetic doses of ketamine, an NMDA receptor antagonist, have been shown to induce rapid (within hours) antidepressant activity that may persist over several days to weeks in patients with pharmacotherapy-resistant MDD and bipolar depression ([Newport et al. 2015](#)). However, rates of antidepressant response to ketamine therapy vary widely, and not all glutamatergic compounds—or even all NMDA receptor antagonists—produce antidepressant effects.

## Neuroendocrine Dysfunction and Maladaptive Responses to Stress

Not surprisingly, depression is marked by dysregulation of important biological systems other than those involved in neurotransmitter signaling. Depressed individuals are often characterized as having altered biological responses to stress, likely due to dysregulation and overstimulation of the HPA axis ([Gold 2015](#)). Early studies showed that administration of dexamethasone to unmedicated depressed persons failed to suppress the secretion of cortisol ([Brown and Shuey 1980](#); [Carroll 1982](#); [Coppen et al. 1983](#)), a condition known as *dexamethasone nonsuppression*. This impairment of HPA axis regulation has been traced to dysregulated corticotropin-releasing hormone (CRH) secretion from the hypothalamus ([Holsboer 2000](#)). Depressed individuals have higher CRH neuronal activity ([Raadsheer et al. 1994](#)) and display a blunted adrenocorticotrophic hormone and cortisol response to infusion of synthetic CRH ([Gispens-de Wied et al. 1993](#); [Gold et al. 1986](#)). Remission of depressive symptoms induces a normalization of responses to dexamethasone

or CRH challenge along with normalization of plasma cortisol levels ([Amsterdam et al. 1988](#); [Arana et al. 1985](#); [Sachar et al. 1970](#)). As noted earlier, dysregulation of HPA axis activity and higher rates of depression are more common in individuals exposed to childhood trauma or abuse ([Ehlert 2013](#); [Heim et al. 2008](#)), suggesting that hyperactivity of the HPA axis during critical periods of brain development leads to higher rates of depression later in life.

This cascade of alterations in the HPA axis, and subsequent increase in glucocorticoids, is thought to be responsible for the structural and functional changes seen in certain limbic structures that are crucial for regulating emotion, motivation, reward, cognitive functioning, and reactivity to stress ([Hamon and Blier 2013](#)). Postmortem and neuroimaging studies have reported significant reductions in gray matter volume and glial density in frontolimbic brain regions, including the hippocampus and prefrontal cortex, in depressed patients ([Arnone et al. 2012](#); [Kempton et al. 2011](#); [Rajkowska 2003](#)). Successful antidepressant therapy has been shown to increase cellular proliferation in these brain regions ([Duman 2004](#); [Warner-Schmidt and Duman 2006](#)), whereas chronically elevated levels of stress and glucocorticoid hormones interfere with normal hippocampal neurogenesis ([Anacker et al. 2013](#)). Dysregulation of the HPA axis, however, has not been observed uniformly across samples of depressed individuals and therefore cannot be considered a sole cause of MDD or other depressive states.

## Neuroimmune Mechanisms

Psychosocial stressors are known to activate not only the HPA axis but also pro-inflammatory responses, which may represent another link between the effects of stress and the onset of MDD ([Haroon et al. 2012](#)). Compared with healthy subjects, depressed patients have been found to have higher levels of inflammatory biomarkers, including higher circulating pro-inflammatory cytokines, such as interleukin 6 (IL-6), IL-1, and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) ([Dantzer et al. 2008](#); [Hiles et al. 2012](#)). Exposure to interferon- $\alpha$  (INF- $\alpha$ ), an inflammatory cytokine used to treat chronic hepatitis C

and neoplastic diseases, can induce depressive symptoms that overlap with MDD ([Capuron et al. 2009](#)) and that can be reduced or prevented by antidepressants ([Baraldi et al. 2012](#); [Udina et al. 2014](#)). Pro-inflammatory cytokines have been shown to activate the HPA axis and to alter the metabolism of monoamine neurotransmitters and glutamate ([Haroon et al. 2012](#)). Antidepressant treatment of depressed patients has been shown to reduce plasma levels of cytokines (IL-1 $\beta$  and possibly IL-6) in some studies but not others ([Hannestad et al. 2011](#); [Hiles et al. 2012](#)), and decreases in pro-inflammatory cytokine levels over time have not always correlated with improvement in depressive symptoms ([Brunoni et al. 2014b](#)). For this reason, a neuroimmune mechanism cannot account for all cases of clinically significant depression or serve as a unified explanation of antidepressant activity.

## Dysfunctional Neurotrophic Responses and Neuroplasticity

Deficiencies in a host of growth factors (neurotrophins) that regulate plasticity in the human brain have also been implicated in the pathophysiology of MDD and of other disease states. More specifically, several types of psychosocial stress have been linked with reduced brain-derived neurotrophic factor (BDNF) signaling in the hippocampus ([Duman and Monteggia 2006](#)). Expression of BDNF and BDNF-related genes is reduced or altered in postmortem brain samples and circulating lymphocytes from depressed persons, and serum BDNF levels are decreased in patients with MDD ([Krishnan and Nestler 2008](#)). Antidepressant treatment and electroconvulsive therapy (ECT) have both been found to produce upregulation of BDNF expression in clinical and preclinical studies ([Brunoni et al. 2014a](#); [Cattaneo et al. 2013](#); [Polyakova et al. 2015](#)). Additionally, preclinical studies have shown that BDNF infused directly into the hippocampus produces antidepressant-like effects that are blocked in animals lacking the BDNF gene ([Krishnan and Nestler 2008](#)). However, infusion of BDNF into other brain regions produces increases in depression-like behaviors ([Krishnan and](#)

[Nestler 2008](#)). Enthusiasm for a “neurotrophic hypothesis” for MDD has been further tempered by negative findings from studies that failed to replicate stress- or antidepressant-induced changes in BDNF expression, by the lack of a satisfactory mechanism through which neurotrophic factors might improve mood in depressed patients, and by findings indicating that decreased neurogenesis is not a sole cause of depression ([Groves 2007](#); [Krishnan and Nestler 2008](#)).

## Genetics and Epigenetics

A variety of susceptibility genes have been investigated in hopes of identifying a genetic profile that will help us to better understand the pathophysiology of MDD and provide novel neurobiological targets for treatment interventions. Candidate gene studies have identified several potential risk genes for MDD, including *BDNF*, *SLC6A4*, *ACE*, *P2RX7*, *TPH2*, *PDE9A*, *PDE11A*, *DISC1*, *NR3C1*, *GRIK3*, and genes for monoamine oxidase A and glycogen synthase kinase-3 $\beta$  ([Fan et al. 2010](#); [Levinson 2006](#); [van Rossum et al. 2006](#); [Yoon and Kim 2010](#)). No single gene has been clearly identified as a cause of MDD ([López-León et al. 2008](#)), and it may be concluded that depressive disorders are likely polygenetic in nature ([Uher 2009](#)). Interactions between genes and environmental factors (including childhood trauma and other adverse life events) may contribute more strongly than either alone to the development of depression ([Caspi et al. 2010](#); [Cohen-Woods et al. 2013](#); [Kendler et al. 1995](#)).

Gene expression is influenced by more than simple variations in DNA sequence. The field of epigenetics investigates changes in gene expression caused by biological processes (such as DNA methylation/demethylation and histone acetylation) that do not change the underlying DNA sequence but instead either activate or deactivate the expression of specific genes. Epigenetic alterations in chromatin structure have been associated with depression-like behaviors in animal models and have been found in postmortem brains of depressed persons ([Nestler et al. 2016](#)). Epigenetic changes can occur in response to environmental insults and stress, resulting in long-lasting effects on gene expression ([Qureshi and](#)

[Mehler 2014](#)). Therefore, epigenetic modifications are candidate mechanisms for stress-induced effects on gene expression, neuronal functioning, and the risk of MDD and other depressive states ([Nestler et al. 2016](#)). Interestingly, treatment with antidepressants has been shown to result in epigenetic changes in genes associated with the risk of MDD, including *BDNF* and *SLC6A4* ([Domschke et al. 2014](#); [Duclot and Kabbaj 2015](#)). Epigenetic (dys)regulation of gene expression may therefore represent not only an important pathophysiological mechanism linking environmental or life stress and the risk of MDD but also an important neurobiological mechanism of antidepressant treatment response.

---

## Treatment Options

---

### Antidepressant Medications

Pharmacotherapy with antidepressants is an important component of a comprehensive biopsychosocial treatment plan for managing MDD. The pharmacological profiles of individual antidepressants are extensively reviewed in [Chapters 8–23](#) of this volume. Our focus in this chapter is the practical aspects of antidepressant use and the broader range of treatments for MDD and other depressive disorders.

#### Choosing the Initial Antidepressant

With regard to initial antidepressant choice, there is little evidence that one antidepressant is clearly superior to other agents under most routine treatment conditions, although there may be some evidence of modest efficacy advantages for venlafaxine or other serotonin-norepinephrine reuptake inhibitors (SNRIs) over selective serotonin reuptake inhibitors (SSRIs) ([Nemeroff et al. 2008](#); [Papakostas et al. 2007b](#); [Schueler et al. 2011](#)) and for sertraline, escitalopram, or mirtazapine over selected other antidepressants ([Cipriani et al. 2008, 2009](#); [Gartlehner et al. 2011](#); [Kennedy et al. 2009](#); [Montgomery et al. 2007](#)). However, there is limited research

supporting differential benefit. Therefore, in most cases, initial antidepressant choice is made on the basis of differential side-effect and tolerability profiles. For example, SSRIs are generally preferred for initial antidepressant treatment in patients with MDD because they are associated with fewer side effects than SNRIs, tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs) (Anderson 2000; Nemeroff et al. 2008; Schueler et al. 2011) and are regarded as being relatively safe in overdose (Barbey and Roose 1998). However, sexual side effects can be treatment limiting with the SSRIs (and with SNRIs, TCAs, MAOIs, vilazodone, and vortioxetine), whereas bupropion and mirtazapine have lower rates of treatment-emergent sexual dysfunction and therefore may be preferred by some patients (Montejo et al. 2015).

Additional factors that may be considered when choosing among antidepressants for treating patients with depressive disorders are summarized in Table 46-2. Drug-drug interactions may increase blood levels of concomitantly administered medications, and at times those interactions can be unpleasant or even life-threatening (Spina et al. 2012). When comorbid psychiatric or medical conditions are present, it may be particularly advantageous to select an antidepressant that effectively addresses both the depression and the comorbid disorder and to avoid antidepressants that may aggravate the comorbid condition. Persons with MDD *with atypical features*—a DSM-5 (American Psychiatric Association 2013) specifier defined as depression with intact mood reactivity and at least two associated symptoms (significant weight gain/increase in appetite, hypersomnia, “lead-like” heaviness in the limbs, sensitivity to perceived rejection)—may respond preferentially to an oral MAOI or to SSRIs (Henkel et al. 2006). For most patients with MDD *with psychotic features* (defined as the presence of hallucinations or delusions), the use of an antidepressant in combination with an antipsychotic drug is more efficacious than antidepressant monotherapy, although the side-effect burden may be greater with combination therapy than with monotherapy (Farahani and Correll 2012).

---

**TABLE 46-2. Factors to consider when selecting an antidepressant for treatment of major depressive disorder**

---

Efficacy profile (no evidence of large differences between agents for routine use)

Side-effect (tolerability) profile

Safety in overdose

Concomitant medications and the potential for drug–drug interactions

Comorbid psychiatric illness(es)

Comorbid general medical illness(es)

Prior treatment response to the medication (efficacy, tolerability)

Family history of treatment response to the medication (efficacy, tolerability)

Patient preference

Medication cost/insurance coverage

---

*Source.* [Cleare et al. 2015](#); [Lam et al. 2009](#); [Malhi et al. 2013](#); [Mann 2005](#).

Compared with the extensive literature on antidepressants in MDD, far fewer studies have focused on antidepressant efficacy in patients with persistent depressive disorder (dysthymia); however, SSRIs and TCAs appear to be effective in this disorder ([Kriston et al. 2014](#)).

## **Assessing and Optimizing Treatment Response**

The initial goals of treatment are to achieve symptom remission (absence of clinically significant depressive symptoms) and to restore normal functioning. Once a patient is well, the primary goals are to prevent relapses and minimize adverse effects.

In general, 2–6 weeks of treatment are required for most antidepressants to show positive clinical benefit, and some patients require an even longer period of time. However, lack of significant clinical benefit by 4 weeks predicts lower odds of an eventual positive treatment response, and a change in treatment may be needed ([Szegedi et al. 2003](#)). Lack of discernible positive treatment response to an antidepressant may reflect inefficacy of the medication for that patient; however, this conclusion can be reached

only after practical reasons for poor response to antidepressant pharmacotherapy have been ruled out ([Table 46-3](#)).

---

**TABLE 46-3. Reasons for poor response to antidepressant pharmacotherapy**

---

Poor adherence to medication (consider therapeutic drug monitoring, where appropriate)
Inadequate dosage (or serum value in the case of certain TCAs)
Inadequate duration of treatment
Inaccurate diagnosis (e.g., secondary depression, bipolar I or II depression)
Undiagnosed psychiatric symptoms (e.g., psychotic or atypical features) or comorbidity (e.g., substance use disorder, personality disorder, anxiety disorder)
New or worsening medical comorbidities
Drug-drug interactions (particularly concomitant medications that may worsen depressive symptoms, aggravate antidepressant side effects, or lead to excessively rapid metabolism of the antidepressant)
Undiagnosed psychosocial factors that are prolonging depressive symptoms

---

*Note.* TCAs=tricyclic antidepressants.

*Source.* [Cleare et al. 2015](#); [Culpepper et al. 2015](#).

Positive antidepressant responses that fall short of remission are clinically meaningful but are also associated with higher rates of relapse and residual functional impairment ([Culpepper et al. 2015](#)). Strategies for managing partial response to antidepressants include incrementally increasing the dosage of antidepressant (assuming good tolerability), adding another medication and/or psychotherapy to the antidepressant (if the dosage of the antidepressant cannot be increased and switching to a new drug carries the risk of a full symptom relapse), or switching to a new antidepressant (if combination pharmacotherapy is infeasible or if side effects are intolerable).

With regard to combination pharmacotherapy to improve efficacy, there is evidence supporting the adjunctive use of lithium with TCAs or possibly SSRIs ([Crossley and Bauer 2007](#); [Zhou et al. 2015](#)); the adjunctive use of selected atypical antipsychotic drugs primarily with SSRIs ([Papakostas et al. 2007a, 2015](#)); and the adjunctive use of thyroid hormone (T<sub>3</sub>, liothyronine) with SSRIs and TCAs ([Zhou et al. 2015](#)). There is also evidence supporting the use of mirtazapine or TCAs in combination with SSRIs in improving remission rates, as compared with SSRIs alone ([Rocha et al. 2012](#)). Other commonly used strategies in clinical practice include augmentation of antidepressants with a second antidepressant (e.g., bupropion, mirtazapine), with buspirone, with modafinil or armodafinil, or with a traditional psychostimulant such as methylphenidate; however, there is less evidence supporting most of these strategies ([Lam et al. 2009](#); [Zhou et al. 2015](#)).

There is some evidence supporting combination pharmacotherapy to manage adverse effects of antidepressants, including bupropion or selected phosphodiesterase inhibitors (sildenafil, tadalafil) for reducing antidepressant-associated sexual side effects ([Taylor et al. 2013](#)), with the best evidence supporting sildenafil for both men and women ([Fava et al. 2006](#); [Nurnberg et al. 2008](#)). Use of adjunctive pharmacotherapy to manage antidepressant-associated side effects may be appropriate if lowering the antidepressant dosage or switching to a new antidepressant is not feasible, provided that adding the second agent does not introduce unacceptable medical risk or drug interactions.

There is controlled evidence supporting the benefit of switching from one SSRI to another after insufficient response to an initial SSRI trial, especially if the first SSRI was poorly tolerated ([Ruhé et al. 2006](#)). Clinical guidelines and controlled evidence also support the benefit of switching to a non-SSRI antidepressant if there is either a lack of clinical benefit from the initial SSRI trial or a lack of response to two SSRI trials ([Cleare et al. 2015](#); [Lam et al. 2009](#); [Malhi et al. 2013](#); [Ruhé et al. 2006](#)). Treatment-resistant depression—defined as depression that has not responded to at least two therapeutic trials of antidepressants from different pharmacological classes (e.g., an SSRI followed by an SNRI, an SSRI followed by

bupropion)—is discussed in the following subsection, “Managing Treatment-Resistant Major Depressive Disorder.”

In general, patients who respond well to an antidepressant at a given dosage should continue at that same dosage for at least 6–9 months. However, there is no broad consensus as to how long antidepressants should be continued in patients whose depressive symptoms remit before a medication-free trial is undertaken. A longer duration of antidepressant treatment may be beneficial for patients who are at higher risk of relapse, including those with a history of multiple depressive episodes. Adjunctive psychotherapy may be useful as an added relapse-preventive measure (see section “Psychotherapies” later in this chapter).

## **Managing Treatment-Resistant Major Depressive Disorder**

Unfortunately, up to one-third of patients with MDD do not respond to at least two therapeutic trials of antidepressants from different pharmacological classes and are considered to have treatment-resistant depression (TRD). Compared with treatment-responsive depression, TRD is associated with more severe and chronic depressive symptoms, greater psychiatric and medical comorbidity, higher health care costs, and higher risks of death from medical illness and suicide ([Greden 2001](#)).

For patients whose depression has not responded to serial therapeutic trials of antidepressants and whose nonresponse cannot be better explained by practical factors (see [Table 46-3](#)), management options include switching antidepressants, using combination pharmacotherapy, augmenting antidepressants with psychotherapy, or initiating a course of ECT. There is support in the literature for switching to a different antidepressant after nonresponse to the current antidepressant at virtually any stage of treatment. For patients with TRD, there is also support for initiating a therapeutic trial of mirtazapine or TCAs (in the case of poor response to other antidepressants), for initiating combination pharmacotherapy with an augmenting agent (e.g., adding an atypical antipsychotic, lithium, or thyroid hormone to the antidepressant), and for switching to an alternative TCA or to an oral

MAOI (in the case of poor response to an initial TCA trial) ([Carvalho et al. 2014](#); [Culpepper et al. 2015](#); [McIntyre et al. 2014](#); [Zhou et al. 2015](#)). Psychotherapy and somatic therapies such as ECT are also treatment options and are reviewed in the following subsections.

There has been recent excitement about the therapeutic potential of ketamine and related glutamatergic NMDA receptor-targeting agents in treatment-resistant unipolar and bipolar depression. When provided at subanesthetic doses, ketamine has shown a rapid onset (within hours) of transient (1–4 weeks) antidepressive effects with very large effect sizes in patients with severely refractive depression ([Newport et al. 2015](#)). However, ketamine therapy for depression is still considered investigational at this time.

## Somatic Therapies

ECT is the best studied of the somatic interventions. It is a clearly one of the treatments of choice for individuals with TRD, and it is effective for MDD with psychotic or catatonic features and for other situations in which a rapid antidepressive effect is needed and lag times to therapeutic benefit with conventional antidepressants are unacceptable (e.g., persons with MDD who are at high suicide risk or those who are nutritionally compromised because of food refusal). Although the mechanism of action of ECT is still not well understood, it is a safe and effective treatment. In repeated studies, ECT has been found to be more effective than placebo (sham ECT) and pharmacotherapy in patients with TRD ([UK ECT Review Group 2003](#)). Adverse cognitive effects and relapses following a successful course (even with ongoing pharmacotherapy) are the main limitations of ECT ([Jelovac et al. 2013](#); [UK ECT Review Group 2003](#)). Relapse rates can be reduced with maintenance ECT. Cognitive side effects may be limited by the use of alternative electrode placements (unilateral instead of bitemporal) and by the use of ultrabrief-pulse (instead of brief-pulse) ECT ([Tor et al. 2015](#)). For a review of recent advances in ECT and other somatic therapies, see [Chapter 45](#) in this volume, “Electroconvulsive Therapy and Other Neuromodulation Therapies,” by McDonald et al.

Vagus nerve stimulation (VNS) was initially developed for the treatment of epilepsy. In 2005 it was approved by the U.S. Food and Drug Administration (FDA) for use in TRD. One of the key findings to emerge from studies of VNS is that its effects may be cumulative, with the full benefits usually not evident until 9–12 months after treatment initiation ([Sackeim et al. 2007](#); [Schlaepfer et al. 2008](#)). VNS is generally available only in specialized settings with adequate surgical capabilities.

Transcranial magnetic stimulation (TMS) was first identified as a treatment for depression in 1995 by a group of National Institute of Mental Health researchers ([George et al. 1995](#)). Since that time, several smaller studies have supported the efficacy of TMS for the treatment of MDD ([Allan et al. 2011](#)). At present, TMS is FDA approved for the treatment of MDD in individuals whose depressive episode has been unresponsive to one adequate medication trial. A number of related neurostimulation treatments are in development, including magnetic seizure therapy, transcranial direct current stimulation, low-field magnetic stimulation, and cranial electrical stimulation ([Rosa and Lisanby 2012](#)).

Deep brain stimulation (DBS) is an FDA-approved treatment for severe, intractable Parkinson's disease, essential tremor, dystonia, and obsessive-compulsive disorder (under a humanitarian device exemption). In a large multisite study of DBS therapy in 20 individuals with TRD, the initial 6-month response and remission rates were 60% and 30%, respectively ([Lozano et al. 2008](#)). Significant reductions in depressive symptoms and high remission rates have subsequently been demonstrated in small open studies of DBS therapy for severely treatment-resistant depression ([Anderson et al. 2012](#)). Despite these encouraging results, there is still an inadequate understanding of the precise mechanisms underlying the therapeutic effects of DBS for TRD, and its use in the treatment of MDD is still considered to be investigational. Furthermore, larger trials of DBS in TRD have not confirmed its efficacy ([Dougherty et al. 2015](#)). As with VNS, longer periods of exposure to DBS may yield better effects ([Holtzheimer et al. 2012](#)).

Bright light therapy appears to be an effective augmentation therapy for certain types of depressive disorders ([Oldham and Ciraulo 2014](#)). Light has been best studied in patients with seasonal

affective disorder (i.e., DSM-5 major depressive episode with seasonal pattern), although it also appears to be effective for some patients with nonseasonal depression (Even et al. 2008). Light therapy for up to 90 minutes per day has been shown to effectively treat—and also to prevent the development of—depressive disorders (Even et al. 2008; Westrin and Lam 2007), especially those with a seasonal pattern. Light therapy has also been shown to improve depressive symptoms in pregnant and postpartum women (Corral et al. 2007; Wirz-Justice et al. 2011).

In summary, ECT is clearly effective for TRD and severe forms of depression, including MDD with psychotic features. VNS and TMS are also approved for the treatment of MDD that has not responded to at least one antidepressant trial. Additional neuromodulatory treatments such as DBS are under clinical development and show considerable promise but are likely to be available only in highly specialized treatment settings. It is clear that more work needs to be done in investigating somatic options for patients with TRD.

## Psychotherapies

### Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is a time-limited psychotherapy that aims to help patients systematically assess and modify distorted (depression promoting) automatic thoughts and assumptions about themselves, their current situation, and their future. These cognitive techniques are coupled with behavioral interventions designed to combat passive disengagement from life activities, including social withdrawal. CBT has been shown to be effective in reducing active symptoms of depression and preventing depressive relapses (Lynch et al. 2010). Although practice guidelines have preferentially recommended antidepressant pharmacotherapy over psychotherapy for severe episodes of MDD, recent evidence has suggested that for patients with nonpsychotic MDD, baseline depression severity may not moderate differences in antidepressive efficacy between CBT and antidepressant pharmacotherapy (Weitz et al. 2015). The combination of CBT with antidepressant pharmacotherapy may be

more effective than medication alone in reducing depressive symptoms and improving recovery rates and adherence to treatment ([Hollon et al. 2014](#)). CBT also appears to be just as effective as continuation medication in preventing relapse after recovery from a depressive episode ([Hollon et al. 2005](#)).

## **Interpersonal Therapy**

Interpersonal psychotherapy (IPT) is a time-limited individual psychotherapy that focuses on four problem areas—grief, role transitions, role disputes, and interpersonal deficits—during acute treatment of depression. IPT has been demonstrated to be an efficacious acute treatment for patients with MDD, both alone and in combination with antidepressant pharmacotherapy ([Cuijpers et al. 2011](#)).

Both IPT and CBT are recommended as first-line psychotherapies for treating patients with MDD, and there is no clear evidence that one is more efficacious than the other ([Jakobsen et al. 2012](#)). However, IPT appears to be effective in reducing relapse only while it is continued ([Frank et al. 2007](#)).

## **Mindfulness-Based Cognitive Therapy**

Mindfulness-based cognitive therapy (MBCT) is a next-generation psychotherapy based in part on cognitive therapy principles, supplemented by techniques that teach depressed patients to adopt a nonjudgmental awareness of the present moment in an effort to disengage from negative thought patterns that maintain depressive episodes and lead to depressive relapses ([van der Velden et al. 2015](#)). MBCT has been shown to be effective in preventing relapse in patients with recurrent MDD, particularly those with three or more lifetime mood episodes ([Piet and Hougaard 2011](#)). The effectiveness of MBCT in treating acute depressive episodes, including acute episodes in patients with severe MDD, has not been established.

## **Other Psychotherapies for Depression**

Other forms of psychotherapy that have been studied in patients with MDD and other forms of depressive illness include behavioral activation, short-term psychodynamic psychotherapy, acceptance

and commitment therapy, motivational interviewing, cognitive-behavioral analysis system of psychotherapy, and self-guided treatments such as bibliotherapy and computer-based delivery platforms for psychotherapy ([Lampe et al. 2013](#); [Parikh et al. 2009](#)). In general, there is much less empirical support for these approaches than for either CBT or IPT; therefore, more high-quality studies are needed.

In conclusion, both CBT and IPT are efficacious in the treatment of MDD. Evidence to date suggests that CBT is also effective in the maintenance treatment of depressive disorders. However, there is still uncertainty about how best to select the most appropriate form of psychotherapy for an individual patient. To a significant degree, the success of IPT and CBT appears to depend on therapist training and competence in delivering the specific form of psychotherapy ([Hollon and Ponniah 2010](#)).

## Other Adjunctive Treatments

### Complementary and Alternative Medicine Approaches

There are a host of complementary and alternative medicine approaches that have been studied for treating patients with MDD and other types of unipolar depression. There is evidence from controlled studies to support the use of *Hypericum perforatum* (St. John's wort) for mild to moderate depression ([Linde et al. 2008](#)), although this agent should not be combined with serotonin-potentiating antidepressants (such as SSRIs, SNRIs, TCAs, or MAOIs) to avoid risk of serotonin syndrome.

There is also some controlled evidence supporting the use of S-adenosylmethionine (SAM-e) alone and omega-3 fatty acid supplementation alone or in combination with antidepressants for mainly mild to moderate depression ([Grosso et al. 2014](#); [Papakostas et al. 2010](#)). Other approaches that have also shown promise include partial wake therapy (sleep deprivation) and supplementation with L-methylfolate, dehydroepiandrosterone (DHEA), tryptophan, or other nutraceuticals. Further controlled research is warranted.

## Lifestyle Interventions

A variety of lifestyle interventions have been systematically evaluated, mainly as adjuncts to core depression treatments. Beneficial effects have been observed for increasing physical activity and exercise; making dietary modifications; maintaining adequate relaxation and sleep practices; practicing mindfulness-based meditation; and reducing or eliminating recreational substance use, including nicotine, drugs, and alcohol ([Sarris et al. 2014](#)). In general, nearly all of these interventions can be recommended for improving general health and well-being in most patients with little risk of harm.

---

## Conclusion

---

Over the past decade, there have been remarkable advances in our knowledge about the neurobiology, course and prognosis, and treatment of MDD and other unipolar depressive illnesses. Some patients with MDD have an episodic course with relatively normal functioning between discrete mood episodes. The majority of patients, however, have a more chronic and persisting course.

Fortunately, there are a large number of first-line treatments for MDD, including a wide variety of antidepressants. Although many patients benefit from treatment with antidepressants, a significant percentage of patients do not respond to a degree that leads to symptomatic remission and full functional recovery. Furthermore, a substantial number of patients do not benefit even after multiple therapeutic trials of antidepressants. For those who respond but do not achieve remission, options for management include implementing dosage increases as tolerated, initiating pharmacological augmentation regimens (combination pharmacotherapy), integrating pharmacotherapy with psychosocial treatments (including CBT or IPT), and switching treatments. For patients with TRD, the same general approaches can be used, although older antidepressants (such as TCAs and MAOIs) and ECT are higher-priority treatment options. Most patients with MDD with psychotic features will require combination pharmacotherapy with

an antidepressant and an antipsychotic drug. Seasonal forms of depression may respond well to light therapy. Adoption of healthy lifestyle habits can be recommended for nearly all patients.

Although the field has made significant progress with regard to depression treatment, many challenges remain, particularly for patients with TRD, for which treatment options are the most limited. However, advances in basic biological investigations of depression are greatly expanding our knowledge, and new psychotherapies and biological treatments continue to be developed. Future research will be focused on integrating findings across multiple neuroscientific disciplines to better elucidate the roles of and interactions between the variety of neurotransmitter-, neuroendocrine-, immune-, neurohormonal-, neurotrophic-, and circuitry-based systems implicated in the pathogenesis of depression. Advances in translational research will identify novel biological targets for depression treatment and will allow us to develop better and more personalized approaches for our patients.

This chapter is an update and revision of Shaywitz J, Rapaport MH: "Treatment of Depression," in *Essentials of Clinical Psychopharmacology*, Third Edition. Edited by Schatzberg AF, Nemeroff CB. Arlington, VA, American Psychiatric Publishing, 2013, pp 577-589.

## CHAPTER 47

# Treatment of Bipolar Disorder

Paul E. Keck Jr., M.D.

Susan L. McElroy, M.D.

In this chapter, we review strategies for treating bipolar disorder, drawing primarily on data from randomized controlled trials. Where such data are lacking, strategies based on data from open trials, naturalistic studies, and expert consensus guidelines are included. The treatment of bipolar disorder in children and adolescents is covered elsewhere in this book (see [Chapter 55](#) in this volume, “Treatment of Child and Adolescent Disorders,” by Wagner and Pliszka).

---

## Treatment of Acute Bipolar Manic and Mixed Episodes

---

Manic and mixed episodes are medical emergencies and frequently require treatment in a hospital to ensure the safety of patients and those around them. The primary goal of treatment of manic and mixed episodes is rapid symptom reduction, followed by full remission of symptoms and restoration of psychosocial and vocational functioning ([Hirschfeld et al. 2002](#)).

Pharmacotherapy is the cornerstone of treatment of acute manic and mixed episodes and of bipolar disorder in general. We review medications that have shown efficacy in the treatment of acute manic and mixed episodes. Although these agents typically produce rates of response (defined as  $\geq 50\%$  reduction in manic symptoms from baseline to endpoint) of approximately 50% in short-term (3- to 4-week) trials, relatively few patients ( $<25\%$ ) actually achieve remission of symptoms within these time intervals while receiving monotherapy with any of these agents. Thus, use of combination therapy is common in clinical practice to improve response and remission rates ([Suppes et al. 2005](#)).

## Lithium

Lithium has been a mainstay of treatment for acute mania for more than 50 years, with superior efficacy compared with placebo (reviewed in [Goodwin and Jamison 2007](#)) and equivalent efficacy compared with divalproex ([Bowden et al. 1994](#)), carbamazepine ([Lerer et al. 1987](#); [Small et al. 1991](#)), risperidone ([Segal et al. 1998](#)), olanzapine ([Berk et al. 1999](#)), quetiapine ([Bowden et al. 2005](#)), aripiprazole ([Keck et al. 2003a](#)), and typical antipsychotics ([Garfinkel et al. 1980](#); [Johnson et al. 1971](#); [Platman 1970](#); [Prien et al. 1972](#); [Shopsin et al. 1975](#); [Spring et al. 1970](#); [Takahashi et](#)

[al. 1975](#)). Lithium produced improvement in psychotic as well as manic symptoms in these trials.

Lithium response for acute mania can be maximized by titrating to plasma concentrations at the upper end of the therapeutic range (1.0–1.4 mmol/L) as tolerated ([Stokes et al. 1976](#)). In randomized controlled trials, significant clinical improvement usually was reported within 7–14 days among responders ([Keck and McElroy 2001](#)). Common side effects associated with acute treatment with lithium include nausea, vomiting, tremor, somnolence, weight gain, and cognitive slowing. Lithium also may interfere with thyroid function and exacerbate renal disease; thus, monitoring of thyroid and renal function tests is an important part of lithium administration.

## Antiepileptics

### Divalproex

Divalproex and related formulations of valproic acid had superior efficacy compared with placebo ([Bowden et al. 1994, 2006](#); [Brennan et al. 1984](#); [Emrich et al. 1981](#); [Pope et al. 1991](#)) and equivalent efficacy compared with lithium ([Bowden et al. 1994](#); [Freeman et al. 1992](#)), haloperidol ([McElroy et al. 1996](#)), and olanzapine ([Zajack et al. 2002](#)) in randomized controlled treatment trials of acute bipolar manic or mixed episodes. Olanzapine was superior to divalproex as measured by mean reduction of manic symptoms and proportion of patients in remission at study completion in a second head-to-head comparison trial ([Tohen et al. 2002a](#)). [Müller-Oerlinghausen et al. \(2000\)](#) found that valproate augmentation of typical antipsychotics led to significantly lower mean antipsychotic dosages and

higher response rates compared with placebo added to typical antipsychotics in patients with acute mania.

Acute antimanic response is correlated with divalproex plasma concentrations between 50 and 125 mg/L, with some evidence of greater response at the upper end of the therapeutic range ([Allen et al. 2006](#); [Zajacka et al. 2002](#)). Some patients may require plasma concentrations greater than 125 mg/L, but side effects become progressively more prevalent above this level. Divalproex administered at a therapeutic starting dosage of 20–30 mg/kg/day has shown good tolerability in inpatients, and some evidence indicates a more rapid response than with gradual titration from a lower (e.g., 750 mg/day) starting dosage ([Hirschfeld et al. 1999](#); [Keck et al. 1993](#)).

Divalproex is generally well tolerated during treatment of acute manic or mixed episodes. Common side effects include somnolence, nausea, vomiting, tremor, weight gain, and cognitive slowing. Enteric-coated and extended-release formulations (the latter requiring a 20% dosage increase to yield plasma concentrations equivalent to those with immediate-release formulations) have improved tolerability compared with valproic acid formulations. Rare serious adverse events include pancreatitis, thrombocytopenia, significant hepatic transaminase elevation, hyperammonemic encephalopathy in patients with urea cycle disorders, and hepatic failure.

## **Carbamazepine and Oxcarbazepine**

An extended-release formulation of carbamazepine was superior to placebo in two large randomized, placebo-controlled multicenter trials ([Weisler et al. 2004b, 2005](#)). These findings replicated earlier results from a placebo-controlled crossover trial ([Ballenger and Post 1978](#)).

Common side effects of carbamazepine include diplopia, blurred vision, ataxia, somnolence, fatigue, and nausea. Less common side effects include rash, mild leukopenia and thrombocytopenia, and hyponatremia. Rare serious adverse events include agranulocytosis, aplastic anemia, hepatic failure, pancreatitis, and exfoliative dermatitis.

In the only large randomized, placebo-controlled multicenter trial of oxcarbazepine in acute mania to date, a 7-week study in children and adolescents, oxcarbazepine was not superior to placebo in reduction of manic symptoms ([Wagner et al. 2006](#)). Thus, the use of oxcarbazepine in acute bipolar mania is not supported by evidence from clinical studies but rather is based on the drug's putative similarities to carbamazepine in mechanism of action and improved tolerability.

## Antipsychotics

### Typical (First-Generation) Antipsychotics

Chlorpromazine ([Klein 1967](#)) and haloperidol ([McIntyre et al. 2005](#)) were superior to placebo in randomized controlled trials. Typical antipsychotics bear the burden of neurological and neuroendocrinological side effects and may carry an increased risk of postmanic depressive episodes ([Kukopulos et al. 1980](#)).

---

## Atypical (Second-Generation) Antipsychotics

---

The atypical antipsychotics olanzapine, risperidone, quetiapine, ziprasidone, aripiprazole, asenapine, and cariprazine have all shown efficacy in the treatment of acute bipolar mania in at least two randomized, placebo-controlled trials.

Olanzapine was found to be superior to placebo ([Tohen et al. 1999, 2000](#)), superior or equal in efficacy to divalproex ([Tohen et al. 2002a](#); [Zajecka et al. 2002](#)), and comparable in efficacy to lithium ([Berk et al. 1999](#); [Niufan et al. 2008](#)), risperidone ([Perlis et al. 2006](#)), and haloperidol ([Tohen et al. 2003a](#)) in mean reduction of manic and mixed symptoms in 3- to 4-week monotherapy trials. Adjunctive treatment with olanzapine was superior to placebo in patients whose symptoms were inadequately responsive to lithium or divalproex monotherapy ([Tohen et al. 2002b](#)). In short-term studies, the most common side effects associated with olanzapine were somnolence, constipation, dry mouth, increased appetite, weight gain, and orthostatic hypotension.

Risperidone was superior to placebo ([Hirschfeld et al. 2004](#); [Khanna et al. 2005](#)) and comparable to olanzapine ([Perlis et al. 2006](#)), haloperidol ([Smulevich et al. 2005](#)), and lithium ([Segal et al. 1998](#)) in mean reduction of manic and mixed symptoms as monotherapy in 3- to 4-week trials. Risperidone was superior to placebo as an adjunctive therapy with lithium or divalproex in one placebo-controlled trial ([Sachs et al. 2002](#)), but not in a second placebo-controlled trial in combination with lithium, divalproex, or carbamazepine ([Yatham et al. 2003](#)). The rate of extrapyramidal side effects (EPS) associated with risperidone was low when the drug was administered at average dosages up to 4 mg/day ([Hirschfeld et al. 2004](#); [Sachs et al. 2002](#); [Yatham et al. 2003](#)), but not when

administered at average dosages of 6 mg/day or greater ([Khanna et al. 2005](#); [Segal et al. 1998](#)). In short-term trials, other commonly occurring side effects included prolactin elevation, akathisia, somnolence, dyspepsia, and nausea.

Quetiapine was superior to placebo as monotherapy in two 12-week studies in adult patients ([Bowden et al. 2005](#); [McIntyre et al. 2005](#)) and was comparable to lithium in a 4-week study in adult patients ([Li et al. 2008](#)). Similarly, quetiapine was superior to placebo as adjunctive treatment with lithium or divalproex ([Sachs et al. 2004](#); [Yatham et al. 2004](#)). The mean modal dosage of quetiapine associated with antimanic efficacy in most studies was approximately 600 mg/day ([Vieta et al. 2005b](#)). Quetiapine was also superior to placebo in the reduction of hypomanic or mild manic symptoms among outpatients in an 8-week trial ([McElroy et al. 2010a](#)). The most common side effects from quetiapine in monotherapy trials were headache, dry mouth, constipation, weight gain, somnolence, and dizziness.

Ziprasidone was superior to placebo (mean dosage=120–130 mg/day) in two 3-week monotherapy trials in adult patients ([Keck et al. 2003b](#); [Potkin et al. 2005](#)) and comparable to haloperidol in a 12-week trial ([Ramey et al. 2003](#)). Ziprasidone was not superior to placebo as an adjunctive treatment with lithium in a study designed to prove superior onset of action by 2 weeks of treatment ([Weisler et al. 2004a](#)). Ziprasidone-related side effects in monotherapy trials included headache, somnolence, EPS, akathisia, and dizziness.

Aripiprazole had significantly greater efficacy in the reduction of manic symptoms compared with placebo in three 3-week trials ([Keck et al. 2003a, 2007](#); [Sachs et al. 2006](#)) and equivalent efficacy compared with haloperidol

([Vieta et al. 2005a](#)) and lithium ([Keck et al. 2009](#)) in adequately powered 12-week comparison trials. Aripiprazole was initiated at 15 or 30 mg/day. Common side effects associated with aripiprazole in the placebo-controlled trials were headache, nausea, vomiting, constipation, insomnia, and akathisia.

Asenapine was superior to placebo in mean reduction of manic symptoms in two 3-week trials ([McIntyre et al. 2009, 2010](#)). Common side effects attributed to asenapine were EPS and mild weight gain.

Cariprazine, a dopamine D<sub>3</sub> and D<sub>2</sub> receptor partial agonist, was superior to placebo in reduction of manic symptoms in three randomized controlled trials ([Calabrese et al. 2015](#); [Durgam et al. 2015](#); [Sachs et al. 2015](#)). The most common side effects associated with cariprazine (occurring in  $\geq 10\%$  of subjects and at twice the rate with placebo) were akathisia, EPS, tremor, dyspepsia, and vomiting.

In the studies of atypical antipsychotics reviewed in this section, no significant differences in response were seen between patients with and patients without psychotic features or between patients with manic episodes and patients with mixed episodes among all agents, with the exception of trials of quetiapine, many of which excluded patients with mixed episodes. The prototypical atypical agent clozapine was reported to have substantial efficacy in several large case series of patients with treatment-refractory mania ([Calabrese et al. 1996](#); [Green et al. 2000](#)) but has not been studied in placebo-controlled trials in mania.

## Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is an important treatment option for manic patients with severe, psychotic, or catatonic symptoms. ECT was superior in efficacy both to lithium ([Small et al. 1988](#)) and to the combination of lithium and haloperidol ([Mukherjee et al. 1994](#)) in prospective comparison studies. In addition, ECT in combination with chlorpromazine was superior to sham ECT and chlorpromazine ([Sikdar et al. 1994](#)). Although these were small studies, their findings are consistent with those of other naturalistic studies of ECT in the treatment of acute mania ([Black et al. 1987](#); [Thomas and Reddy 1982](#)). There is a risk of neurotoxicity in patients receiving ECT while also receiving lithium; thus, lithium should be discontinued when ECT is administered ([Hirschfeld et al. 2002](#)).

## Novel Treatments

In two short-term monotherapy pilot trials ([Yildiz et al. 2008](#); [Zarate et al. 2007](#)) and one adjunctive therapy trial ([Amrollahi et al. 2011](#)), the protein kinase C inhibitor tamoxifen was superior to placebo in reduction of manic symptoms.

Placebo-controlled trials of the extended-release formulation of the atypical antipsychotic paliperidone in acute mania have thus far yielded mixed findings ([Berwaerts et al. 2011, 2012b](#); [Vieta et al. 2010](#)).

---

## Treatment of Acute Bipolar Depressive Episodes

---

The goal of treatment of bipolar depression is full remission of symptoms ([Hirschfeld et al. 2002](#)). This straightforward goal is complicated by the limited efficacy of many mood stabilizers in bipolar depression ([Zornberg and Pope 1993](#)), often requiring the adjunctive use of unimodal antidepressants with the attendant risk of cycle acceleration or switching.

## Lithium

Eight of nine placebo-controlled trials conducted in the 1960s and 1970s in patients with bipolar I and II disorders found lithium superior to placebo in acute bipolar depression (reviewed in [Zornberg and Pope 1993](#)). In an analysis of five studies in which it was possible to distinguish “unequivocal” lithium responders from patients who had partial but incomplete improvement in depression, [Zornberg and Pope \(1993\)](#) reported that 36% had an unequivocal response, compared with 79% who had partial but incomplete benefit.

## Atypical Antipsychotics

### Quetiapine

Quetiapine (300 mg/day and 600 mg/day) was superior to placebo in reduction of depressive symptoms in four large 8-week multicenter trials involving outpatients with bipolar I and II depression ([Calabrese et al. 2005a](#); [McElroy et al. 2010b](#); [Thase et al. 2006](#); [Young et al. 2010](#)). No significant difference in efficacy was found between the two quetiapine dosage groups. However, the rate of side effects was lower

in the 300 mg/day groups compared with the 600 mg/day groups. Switch rates were low across all treatment groups and were not significantly different among the quetiapine and placebo groups.

## **Olanzapine and Olanzapine-Fluoxetine Combination**

Olanzapine and the combination of olanzapine and fluoxetine (OFC) were superior to placebo in reducing depressive symptoms in an 8-week trial of 833 patients with bipolar I depression ([Tohen et al. 2003c](#)). However, the OFC was superior not only to placebo throughout the trial but also to olanzapine for weeks 4 through 8. No significant differences in switch rates (6%–7%) were found among the three groups. [Brown et al. \(2006\)](#) compared OFC with lamotrigine (titrated to 200 mg/day) in a 7-week comparison trial in outpatients with bipolar I depression. Patients receiving OFC had greater reductions in depressive symptoms compared with patients receiving lamotrigine, although the lamotrigine group may have had a greater response with a longer trial, given the need for gradual lamotrigine titration. Switch rates were not significantly different between the two groups.

## **Lurasidone**

Findings from two placebo-controlled trials indicate that lurasidone is efficacious in the treatment of bipolar I depressive episodes (reviewed by [Franklin et al. 2015](#)). Notably, the onset of therapeutic effect occurred within the first 2–3 weeks of treatment among responders. Safety data from these trials also suggest that lurasidone is significantly

less likely than other atypical agents to produce metabolic side effects.

## Antiepileptics

### Lamotrigine

In an initial large 7-week randomized, placebo-controlled trial, lamotrigine (at 50 mg/day and 200 mg/day) was superior to placebo in patients with bipolar I depression ([Calabrese et al. 1999](#)). Switch rates (3%–8%) were not significantly different among the three groups. A second large placebo-controlled, parallel-group, flexible-dose trial involving patients with bipolar I and II depression did not find a significant advantage for lamotrigine over placebo ([Bowden 2001](#)). In a double-blind crossover trial, [Frye et al. \(2000\)](#) found lamotrigine superior to placebo in improving depression in patients with treatment-refractory rapid-cycling bipolar I or II disorder. Lamotrigine was superior to placebo when added to lithium treatment in an 8-week trial in patients with breakthrough depressive episodes ([van der Loos et al. 2009](#)). Common side effects of lamotrigine in these studies included headache, nausea, infection, and xerostomia. The risk of serious rash from lamotrigine can be reduced by carefully adhering to recommended titration schedules ([GlaxoSmithKline 2016](#)), but patients should be warned of the risk of rash and of the need to report any such symptoms immediately.

### Carbamazepine

In two small controlled trials in patients with treatment-refractory bipolar depression, response to carbamazepine

was superior to that seen with placebo (Post et al. 1986) or lithium ([Small 1990](#)). The results of these initial intriguing findings have not been followed by large placebo-controlled, parallel-group studies.

## **Divalproex**

Two small randomized, placebo-controlled trials of divalproex in the treatment of acute bipolar depression yielded opposite findings. [Sachs and Collins \(2001\)](#) did not find divalproex to be superior to placebo in one pilot trial, whereas [Davis et al. \(2005\)](#) found divalproex superior to placebo in reduction of depressive and anxiety symptoms in a later pilot study.

## **Antidepressants**

Because of the meager evidence base, current recommendations regarding the use of antidepressants in conjunction with mood stabilizers for acute bipolar I depression tend toward the conservative (i.e., avoid antidepressants if possible). However, some general impressions can be gleaned from the available clinical trials. First, switch rates associated with newer antidepressants in short-term trials, in general, appear to be lower than those associated with tricyclic antidepressants (TCAs) in older studies ([Thase and Sachs 2000](#)). Second, among all of the antidepressants studied, the most substantial evidence for efficacy rests with the monoamine oxidase inhibitor (MAOI) tranylcypromine ([Himmelhoch et al. 1991](#)), but safety concerns often eliminate this agent from first-line therapy choices ([Hirschfeld et al. 2002](#)). Bupropion ([Sachs et al. 1994](#)) and

selective serotonin reuptake inhibitors (SSRIs) ([Nemeroff et al. 2001](#)) are common first-line agents administered in conjunction with mood stabilizers.

## Electroconvulsive Therapy

ECT had significantly greater efficacy than MAOIs, TCAs, or placebo in several randomized controlled trials in patients with bipolar depression (reviewed in [Zornberg and Pope 1993](#)). ECT may be particularly indicated for patients with severe, psychotic, or catatonic symptoms.

## Psychotherapy

Very few randomized controlled trials of any form of psychotherapy for patients with acute bipolar depression have been conducted. Cognitive-behavioral and interpersonal therapy have demonstrated efficacy in the treatment of unipolar major depression, but these modalities have been examined only in very small preliminary studies in patients with bipolar depression, thus far without conclusive findings ([Cole et al. 2002](#); [Zaretsky et al. 1999](#)).

## Novel Treatments

Two preliminary placebo-controlled trials found the dopamine D<sub>2</sub> and D<sub>3</sub> receptor agonist pramipexole superior to placebo in the adjunctive treatment of depression in patients with bipolar I or bipolar II disorder ([Goldberg et al.](#)

2004; Zarate et al. 2004). Switch rates with pramipexole did not differ significantly from those with placebo.

In a 1-week placebo-controlled trial, Watson et al. (2012) examined the efficacy of mifepristone in improvement in spatial working memory in 60 patients with bipolar depression. They found that mifepristone (600 mg/day) treatment was associated with sustained improvement in spatial working memory as an independent variable apart from improvement in depressive symptoms.

---

## Maintenance Treatment

---

Bipolar disorder is a recurrent lifelong illness in more than 90% of the patients who experience a manic episode (Goodwin and Jamison 2007). Because of the high risk of recurrence and morbidity associated with mood episodes and interepisode symptoms, maintenance treatment is usually recommended after a single manic episode (Hirschfeld et al. 2002). The goals of maintenance treatment include prevention of syndromal relapse and subsyndromal symptoms, optimization of functioning, and prevention of suicide.

### Lithium

Lithium is the most extensively studied medication in the maintenance treatment of bipolar disorder. Data from randomized, placebo-controlled trials conducted in the 1960s and 1970s indicated that lithium protected against relapse, with a fourfold lower risk compared with placebo at 6-month and 1-year follow-up (Keck et al. 2000). Lithium

was superior to placebo in preventing relapse into mania in two randomized controlled parallel-group trials lasting 18 months ([Bowden et al. 2003](#); [Calabrese et al. 2003](#)).

The optimal maintenance lithium serum concentration is an important consideration in successful maintenance treatment. Maintenance lithium serum concentrations usually are lower than those required to produce acute antimanic efficacy. However, studies by [Gelenberg et al. \(1989\)](#) and [Keller et al. \(1992\)](#) found a serum level-response relationship, with levels of 0.4–0.6 mEq/L being associated with 2.6 times the relapse rate and a significantly greater likelihood of experiencing subsyndromal symptoms compared with levels of 0.8 mEq/L or higher. There was also a serum level-side effect relationship, with patients at higher levels experiencing significantly higher rates of side effects, often leading to discontinuation. [Perlis et al. \(2002\)](#), in yet another reanalysis of the [Gelenberg et al. \(1989\)](#) data, reported that an abrupt drop in serum lithium levels, whether due to random reassignment or to nonadherence, was the most powerful predictor of relapse. The optimal lithium level for many patients will be the level that balances relapse prevention and suppression of subsyndromal symptoms against minimization of bothersome day-to-day side effects.

## Antiepileptics

Two large 18-month placebo-controlled maintenance trials comparing lamotrigine (200–400 mg/day) with lithium (0.8–1.1 mEq/L) found lamotrigine, but not lithium, superior to placebo in preventing depressive episodes ([Bowden et al. 2003](#); [Calabrese et al. 2003](#)). In contrast, lithium, but not

lamotrigine, was superior to placebo in preventing manic episodes. Of the nearly 1,200 patients who received lamotrigine in these trials, 9% developed a benign rash (morbilliform or exanthematous eruptions), compared with 8% of the 1,056 patients receiving placebo. When patients who received lamotrigine during the open-label run-in phase of the studies were included in the analysis, the total incidence of rash was 13%, with two cases of serious rash requiring hospitalization ([Calabrese 2002](#)).

[Calabrese et al. \(2000\)](#) conducted a 6-month placebo-controlled relapse prevention study of lamotrigine (mean dosage=288 mg/day) in 182 patients with rapid-cycling bipolar I or II disorder. There was no significant difference between the lamotrigine and the placebo treatment groups in time to need for additional medications for recurrent mood symptoms.

The only randomized, placebo-controlled maintenance study of divalproex in bipolar I disorder found no significant difference in time to development of any mood episode among patients receiving divalproex, lithium, or placebo ([Bowden et al. 2000](#)). A number of unforeseen methodological limitations in this trial complicated interpretation of its results. Among patients who received divalproex for treatment of the index manic episode in an open treatment period prior to randomization, divalproex was superior to placebo on rates of early termination due to any mood episode (29% vs. 50%) during the subsequent year. Divalproex was also compared with olanzapine in a 47-week blinded maintenance trial ([Tohen et al. 2003b](#)). [Calabrese et al. \(2005b\)](#) compared divalproex with lithium in a 20-month study of patients with rapid-cycling bipolar disorder and found comparable relapse rates in both treatment groups.

There are no data regarding the optimal maintenance valproic acid concentration in bipolar disorder. Current practice usually consists of titrating to therapeutic serum concentrations (50–125 µg/mL) and, as with lithium, balancing relapse and subsyndromal symptom prevention against minimization of side effects ([Hirschfeld et al. 2002](#)). Treatment with valproate appears to pose an increased risk of polycystic ovarian syndrome (PCOS), although the relationship between PCOS and weight gain as a possible mechanism is unclear ([Hirschfeld et al. 2002](#)).

Although a number of studies have examined the efficacy of carbamazepine in the maintenance treatment of bipolar disorder, most of these studies yielded results that were difficult to reliably interpret on methodological grounds ([Dardennes et al. 1995](#)).

## Atypical Antipsychotics

Olanzapine was comparable to divalproex in a 47-week comparison trial ([Tohen et al. 2003b](#)) and to lithium in a 1-year comparison trial ([Tohen et al. 2005](#)). Olanzapine received an indication for maintenance treatment in bipolar disorder based on superiority over placebo in prevention of manic and depressive episodes over 48 weeks ([Tohen et al. 2006](#)). The combination of olanzapine and lithium or divalproex was superior to placebo and lithium or divalproex in relapse prevention over 18 months in patients who had initially responded to the active combination acutely ([Tohen et al. 2002b](#)) and then were re-randomized ([Tohen et al. 2004](#)). However, patients in the combination therapy group had twice the weight gain of patients in the monotherapy group.

Aripiprazole was superior to placebo in preventing manic relapse over a 6-month follow-up period in patients with bipolar disorder who were initially stabilized on aripiprazole monotherapy for an acute manic or mixed episode ([Keck et al. 2006, 2007](#)). By contrast, no significant difference between aripiprazole and placebo was found for rates of depressive relapse. However, the overall low rate of depressive relapse in this trial may have been due to the inclusion of patients whose index episodes were manic or mixed rather than depressive.

Two 104-week adjunctive placebo-controlled trials found quetiapine in combination with lithium or divalproex to be superior to placebo with lithium or divalproex in prolonging time to recurrence of a mood episode ([Suppes et al. 2009](#); [Vieta et al. 2008](#)). The quetiapine combination groups also had lower proportions of patients experiencing a mood event.

In a 6-month maintenance trial, ziprasidone was superior to placebo in combination with lithium or divalproex in prolonging time to intervention for a mood episode and in proportion of patients requiring an intervention during the length of the trial ([Bowden et al. 2010](#)).

In two randomized controlled trials, risperidone (long-acting injectable formulation) was found to be superior to placebo in prevention of relapse, both as monotherapy and as adjunctive therapy ([Quiroz et al. 2010](#); [Vieta et al. 2012](#)).

Evidence from one placebo-controlled trial suggests that paliperidone extended release may be efficacious as a maintenance treatment in patients with bipolar disorder ([Berwaerts et al. 2012a](#)).

## Electroconvulsive Therapy

The use of ECT in the maintenance treatment of bipolar disorder has never been studied systematically in a randomized controlled trial. However, several naturalistic studies suggest that maintenance ECT may be a useful treatment alternative for patients whose symptoms are inadequately responsive to pharmacotherapy ([Schwarz et al. 1995](#); [Vanelle et al. 1994](#)).

## Psychotherapy

Most patients with bipolar disorder experience a common cluster of psychological problems stemming directly from the illness. A number of specific psychosocial interventions as adjuncts to mood stabilizer therapy have been shown to improve the long-term outcome of bipolar disorder (reviewed in [Rizvi and Zaretsky 2007](#)). The best-studied interventions include educational, interpersonal, family, and cognitive-behavioral therapies. Randomized controlled trials conducted over 1- to 2-year follow-up periods support the efficacy of cognitive-behavioral therapy ([Lam et al. 2005](#)), family-focused and related forms of therapy ([Clarkin et al. 1990, 1998](#); [Miklowitz et al. 2003](#); [Rea et al. 2003](#)), interpersonal and social rhythm therapies ([Frank et al. 2005](#)), and group psychoeducation ([Colom et al. 2003](#)) in reducing or delaying mood episode recurrence, increasing treatment adherence, and improving functioning. Family-focused, interpersonal, and social rhythm therapies were all associated with delaying time to depressive episode relapse compared with brief treatment ([Miklowitz et al. 2007](#)).

---

## Conclusion

---

There have been substantial advances in the pharmacological treatment of bipolar disorder in the past two decades. A number of medications have demonstrated efficacy in the treatment of acute mania in placebo-controlled trials, either as monotherapy or as an adjunct to mood stabilizers. In addition, available data indicate that combination therapy with an antipsychotic and a mood stabilizer is more rapidly effective, with better overall response rates in acute mania, than either mood stabilizers or antipsychotics alone.

The treatment of bipolar depression remains one of the least-studied aspects of the illness. The “mood stabilizer first” strategy and the combined use of mood stabilizers and antidepressants in moderate to severe bipolar depression are common approaches.

Most patients with bipolar disorder require treatment with more than one medication during the course of their illness. The efficacy of combination strategies is only now receiving close scrutiny. Recent studies suggest that for some patients, the use of combinations of antidepressants and mood stabilizers as maintenance treatment may be important to prevent depressive relapse.

The role and efficacy of different types of psychotherapy at different phases of illness management in bipolar disorder are now becoming clearly established. These components of treatment are important in educating patients and families, improving insight and treatment adherence, enhancing coping skills, and dealing with the sequelae of mood symptoms and episodes—and, it is hoped, improving functioning and outcome. Treatment advances in bipolar disorder are finally occurring rapidly. Bringing these treatments to patients with bipolar disorder is both

the challenge and the reward of helping people manage this illness.

## CHAPTER 48

# Treatment of Anxiety and Related Disorders

Daniella David, M.D.

Jonathan R.T. Davidson, M.D.

Over the past two decades, there has been substantial progress in the treatment of anxiety and related disorders. In this chapter, we review the main findings from double-blind and some open-label trials in each disorder.

---

## Panic Disorder

---

Treatment outcome in panic disorder can be measured with the Panic Disorder Severity Scale (PDSS), which can be administered both as a clinician-rated and as a self-rated scale ([Shear et al. 1997](#)). Other widely used measures include the Sheehan Panic and Anticipatory Anxiety Scale (PAAS; [Sheehan 1986](#)) and the self-rated Marks-Mathews

Fear Questionnaire (FQ; [Marks and Mathews 1979](#)). Although not always attainable, the desired endpoint is full remission. Effective treatment results in reduced emergency department and laboratory resource utilization ([Roy-Byrne et al. 2001](#)).

## First-Line Drug Treatments

### Selective Serotonin Reuptake Inhibitors

In 1995, [Boyer](#) reported that selective serotonin reuptake inhibitor (SSRI) drugs were more effective than imipramine and alprazolam in treating panic disorder, although a meta-analysis by [Otto et al. \(2001\)](#) failed to confirm these findings. Evidence is now available in support of citalopram ([Wade et al. 1997](#)), escitalopram ([Stahl et al. 2003](#)), fluoxetine ([Michelson et al. 1998, 2001](#)), fluvoxamine ([Asnis et al. 2001](#); [Black et al. 1993](#)), paroxetine ([Ballenger et al. 1998](#); [Oehrberg et al. 1995](#); [Sheehan et al. 2005](#)), and sertraline ([Londborg et al. 1998](#)), and also the nonselective serotonin reuptake inhibitor clomipramine ([Lecrubier and Judge 1997](#)). Fluoxetine, paroxetine, and sertraline have been approved by the U.S. Food and Drug Administration (FDA) for treatment of panic disorder.

Patients with panic disorder are often extremely sensitive to activating effects of antidepressants; have poor tolerance of symptoms such as palpitations, sweating, and tremor; and frequently discontinue treatment or drop out. This problem can almost always be prevented by coprescribing a benzodiazepine ([Goddard et al. 2001](#); [Pollack et al. 2003](#)) or by starting with low dosages of an SSRI and increasing them gradually as tolerated. Physician availability and thorough preparation and education of patients are crucial.

Other common side effects of SSRIs include weight gain, sexual dysfunction, impairment of sleep, and potential drug-drug interactions.

Discontinuation of treatment can lead to relapse, which mimics panic symptoms and is quite distressing. Gradual dosage reduction is recommended, as are patient education, physician availability, and coping strategies, including behavior therapy ([Otto et al. 1993](#)). Switching to a long-acting SSRI such as fluoxetine may be considered. Serotonin 2 (5-HT<sub>2</sub>) or serotonin 3 (5-HT<sub>3</sub>) receptor antagonists, such as mirtazapine, nefazodone, and ondansetron, may be used to limit some of the symptoms that are mediated through these pathways (e.g., insomnia, agitation, gastrointestinal distress).

## **Benzodiazepines**

The [Cross-National Collaborative Panic Study \(1992\)](#) showed that alprazolam, along with imipramine, was more effective than placebo in panic disorder; [Lydiard et al. \(1992\)](#) showed that alprazolam 2 mg/day was more effective than placebo. Efficacy for clonazepam was also demonstrated in panic disorder ([Davidson and Moroz 1998](#); [Rosenbaum et al. 1997](#); [Tesar et al. 1991](#)), and its use for this indication is now FDA approved.

Alprazolam is now regarded as a second-line treatment. Problems include sedation at higher dosages, abuse liability, and discontinuation-related distress. Comparable efficacy and tolerability have been demonstrated for the sustained-release formulation of alprazolam ([Pecknold et al. 1994](#); [Schweizer et al. 1993](#)), with decreased likelihood of adverse discontinuation effects.

Clonazepam has an advantage over alprazolam due to its longer half-life; however, it can also produce sedation, depression, and discontinuation symptoms. [Bandelow et al. \(1995\)](#) showed that reduction of panic attacks is an unsatisfactory marker of treatment benefits and therefore should not be relied on as the principal outcome measure. Substantial improvement of quality of life and work productivity were demonstrated in the clonazepam trials compared to placebo ([Jacobs et al. 1997](#)). A recent review supports a role for clonazepam alone or in combination with SSRIs and/or cognitive-behavioral therapy (CBT) in the management of panic disorder ([Nardi et al. 2013](#)).

A particular concern with benzodiazepines is their use in the elderly, who are more prone to sedation and falls that can result in fractures and potential head injury, and who are also more likely to experience discontinuation problems.

## Other Pharmacological Approaches

### Tricyclic Antidepressants

Although tricyclic antidepressants (TCAs) are effective ([Andersch et al. 1991](#); [Cross-National Collaborative Panic Study 1992](#); [Fahy et al. 1992](#); [Lecrubier et al. 1997](#); [Lydiard et al. 1993](#); [Mavissakalian and Perel 1989](#); [Modigh et al. 1992](#)), they are considered second-line treatments for panic disorder because of their side effects. [Mavissakalian and Perel \(1995\)](#) found that phobic symptoms responded best if the plasma level of imipramine and desmethyylimipramine was in the range of 110–140 ng/mL, whereas control of panic attacks tended to occur at lower plasma levels. As with SSRIs, low starting dosages in the range of 10–25

mg/day are in order, with gradual titration thereafter as per patient tolerance.

## **Monoamine Oxidase Inhibitors**

[Sheehan et al. \(1980\)](#) found that phenelzine, along with imipramine, was more effective than placebo in the treatment of panic disorder with agoraphobia, and [Lydiard and Ballenger \(1987\)](#) noted that monoamine oxidase inhibitors (MAOIs) may be superior to TCAs. Although MAOIs may still be the best treatment for some patients, the overall role of MAOIs in managing anxiety disorders is now fairly small because of their potential side effects and drug-drug interactions. The role of the safer reversible inhibitors of monoamine oxidase A (RIMAs) in panic disorder is unclear.

## **Other Drugs**

The extended-release (XR) formulation of venlafaxine, a serotonin-norepinephrine reuptake inhibitor (SNRI), demonstrated greater efficacy than placebo in patients with panic disorder in a 10-week trial ([Bradwejn et al. 2005](#)), was as effective as paroxetine in a 12-week placebo-controlled trial ([Pollack et al. 2007](#)), and has received FDA approval for the treatment of panic disorder. The drug is well tolerated, with an adverse-effect profile comparable to that of the drug in depression and other anxiety disorders.

Mirtazapine, a noradrenergic and specific serotonergic antidepressant, demonstrated possible benefit in panic disorder in open trials ([Boshuisen et al. 2001](#); [Sarchiapone et al. 2003](#)) and in a double-blind comparison with fluoxetine ([Ribeiro et al. 2001](#)); however, double-blind, placebo-controlled trials have yet to be conducted. It is

noteworthy that mirtazapine has been associated with the induction of panic attacks in depressed patients undergoing dosage escalation and discontinuation ([Berigan 2003](#); [Klesmer et al. 2000](#)).

Reboxetine, a selective noradrenergic reuptake inhibitor, has been found to produce greater improvement than placebo in patients with panic disorder ([Versiani et al. 2002](#)), and in general to be well tolerated. In a more recent randomized, single-blind study comparing reboxetine with paroxetine, paroxetine was more effective for panic attacks, but no differences between the treatments were noted for anticipatory anxiety and avoidance ([Bertani et al. 2004](#)). These findings suggest perhaps different roles of norepinephrine and serotonin in the treatment of panic disorder. However, the selective noradrenergic reuptake inhibitor maprotiline appears to be ineffective in panic disorder ([Den Boer and Westenberg 1988](#)), whereas the data for bupropion are inconclusive ([Sheehan et al. 1983](#); [Simon et al. 2003](#)).

Trazodone was less effective than imipramine and alprazolam in the treatment of panic disorder ([Charney et al. 1986](#)). The 5-HT<sub>1A</sub> partial agonist buspirone and the anticonvulsant gabapentin were generally ineffective in panic disorder ([Pande et al. 2000](#); [Sheehan et al. 1990](#)). Possible benefit has been reported in open-label trials for other anticonvulsant drugs, including levetiracetam, tiagabine, and valproic acid ([Keck et al. 1993](#); [Papp 2006](#); [Zwanzger et al. 2001](#)). A small double-blind, placebo-controlled trial with tiagabine did not show clinical benefits, although cholecystokinin-tetrapeptide (CCK-4)-induced sensitivity to panic attacks decreased ([Zwanzger et al. 2009](#)).

Preliminary data suggest improvement in refractory panic disorder when atypical antipsychotics are used as augmentation of SSRI treatment (olanzapine: [Sepede et al. 2006](#); risperidone: [Simon et al. 2006](#)) or in higher dosages as monotherapy (olanzapine: [Hollifield et al. 2005](#)). A single-blind comparison trial comparing paroxetine and low-dose risperidone found the low-dose risperidone to be as effective as paroxetine in the treatment of panic attacks ([Prosser et al. 2009](#)); however, double-blind, placebo-controlled trials are needed. In a recent randomized, placebo-controlled monotherapy trial of quetiapine XR versus divalproex extended release in bipolar patients with comorbid panic disorder or generalized anxiety disorder, quetiapine XR at a dosage range of 50–300 mg/day showed rapid and sustained effects in reducing anxiety symptoms ([Sheehan et al. 2013](#)).

Metabotropic glutamate type 2 receptor agonists have shown promise in preclinical models of anxiety but have yet to demonstrate clinical efficacy in panic disorder ([Bergink and Westenberg 2005](#)). Similarly, the effect of a cholecystokinin-B receptor antagonist was no different from placebo in patients with panic disorder ([Pande et al. 1999a](#)).

## Long-Term Management

Maintenance treatment is recommended for at least 12–24 months, if not longer. In a controlled trial of paroxetine, clomipramine, and placebo, 84% of the paroxetine-treated patients eventually became panic free over the 9-month period ([Lecrubier and Judge 1997](#)). In a 4-year naturalistic follow-up study of 367 patients with panic disorder, greater

improvements in panic attacks, phobic avoidance, and daily functioning were observed in those who received continuation treatment for 4 years, compared with 1 year ([Katschnig et al. 1995](#)), suggesting that recovery continues over several years.

Long-term randomized controlled trials have reported efficacy for citalopram ([Lepola et al. 1998](#)), clomipramine ([Fahy et al. 1992](#)), fluoxetine ([Michelson et al. 1999](#)), paroxetine ([Lecrubier and Judge 1997](#); [Lydiard et al. 1998](#)), and sertraline ([Rapaport et al. 2001](#)). In a relapse prevention trial following 3 months of successful open-label treatment, [Ferguson et al. \(2007\)](#) showed that over the course of 7 months, relapse on venlafaxine XR was 22%, compared with 50% on placebo.

## Discontinuation

Even though there is some similarity between symptoms of relapse and symptoms of drug withdrawal, the existence of discontinuation symptoms is unarguable. A slow taper is recommended (for some benzodiazepines, it may be necessary to taper the drug over weeks or months). Timing of the taper may be important—it is best done when other variables in a patient's life are as stable as possible. Switching to a longer-acting benzodiazepine such as clonazepam, adding an anticonvulsant such as carbamazepine or valproate ([Pages and Ries 1998](#)), and utilizing behavior therapy ([Otto et al. 1993](#)) have all been used to ameliorate discontinuation symptoms.

Various elaborations of CBT have demonstrated consistent efficacy for panic disorder, with the common elements being education, cognitive strategies, and

exposure to feared sensations and situations ([Clum et al. 1993](#); [Royal Australian and New Zealand College of Psychiatrists Clinical Practice Guidelines Team for Panic Disorder and Agoraphobia 2003](#)). CBT is a first-line choice, and even when pharmacotherapy is given as the main treatment, principles of CBT should be incorporated into the management plan. It can be of benefit during the process of drug discontinuation, and perhaps in lessening the chance of relapse afterwards.

---

## **Social Anxiety Disorder (Social Phobia)**

---

Social anxiety disorder (SAD) has a lifetime prevalence of 12% ([Kessler et al. 2005b](#)). It can be grouped into generalized and nongeneralized types. Generalized SAD is more common in clinical settings, is usually more disabling, and is associated with greater levels of comorbidity and genetic loading. Most of our knowledge about pharmacotherapy for SAD derives from the generalized type, and the literature suggests that different medication approaches may be called for in treating the two subtypes.

Comprehensive treatment of SAD requires that the symptoms of fear, avoidance, and physiological distress are brought under control; comorbidity is treated; disability and impairment are improved; and quality of life is enhanced. Furthermore, evidence from maintenance and relapse prevention studies has confirmed the value of long-term therapy in treatment responders.

Instruments commonly used to measure treatment change in SAD include the clinician- and self-rated

Liebowitz Social Anxiety Scale (LSAS; [Liebowitz 1987](#)), which assesses 24 performance or interpersonal situations for fear and avoidance. A score of 30 or less is considered to equate with remission. The Social Phobia Inventory (SPIN) is a 17-item self-rating instrument that assesses fear, avoidance, and physiological distress ([Connor et al. 2000](#)) and, like the LSAS, is able to detect treatment differences.

## Pharmacotherapy

Most clinicians consider SSRIs as the first choice for generalized SAD and  $\beta$ -blockers or benzodiazepines as the first choice for nongeneralized SAD. Second-line drugs for generalized SAD comprise the benzodiazepines, venlafaxine (an SNRI), and perhaps other antidepressants, including nefazodone, mirtazapine, and MAOIs. Bupropion and TCAs have been generally disappointing.

### Serotonergic Drugs

[Van Vliet et al. \(1994\)](#) showed fluvoxamine's superiority over placebo, with response rates of 46% and 7%, respectively. [Stein et al. \(1999\)](#) confirmed the efficacy of fluvoxamine relative to placebo on all symptom domains (i.e., fear, avoidance, and physiological arousal). Controlled-released (CR) fluvoxamine was likewise found to be superior to placebo ([Davidson et al. 2004c](#); [Westenberg et al. 2004](#)), and a study in Japan also found fluvoxamine to be effective versus placebo in reducing SAD symptoms and psychosocial disability ([Asakura et al. 2007](#)).

Sertraline also has been studied ([Blomhoff et al. 2001](#); [Katzelnick et al. 1995](#); [Liebowitz et al. 2003](#); [Van Ameringen et al. 2001](#); [Walker et al. 2000](#)). In the study by

[Van Ameringen et al. \(2001\)](#), 53% of patients responded to sertraline as compared with 29% to placebo, and sertraline-treated patients showed improvement on all three symptom domains of the Brief Social Phobia Scale. In a primary care setting, [Haug et al. \(2000\)](#) showed that cognitive therapy and sertraline could be effectively delivered, although the combination did not show any superiority over treatment with drug alone.

Paroxetine's superiority relative to placebo in SAD has been shown in both short-term efficacy and relapse prevention studies. In the short-term studies by [Stein et al. \(1998\)](#), [Allgulander \(1999\)](#), and [Baldwin et al. \(1999\)](#), rates of response to paroxetine were 55%, 70%, and 66%, respectively, as compared with placebo response rates of 24%, 8%, and 32%. All subjects in the paroxetine trials fulfilled criteria for generalized SAD and showed benefit on the LSAS within 2–4 weeks. Paroxetine CR was also shown to be effective (using LSAS as the primary outcome measure) and well tolerated in a 12-week double-blind, placebo-controlled trial ([Lepola et al. 2004](#)).

Fluoxetine, while superior to placebo on primary outcomes in one study ([Davidson et al. 2004c](#)), failed to separate from placebo in another study ([Kobak et al. 2002](#)), showing a relatively high placebo response rate (30%). Another study found cognitive therapy to be superior to both fluoxetine plus exposure exercises and placebo plus exposure exercises on SAD measures, with no difference between the latter two groups ([Clark et al. 2003](#)). Another serotonergic agent, nefazodone, also failed to separate from placebo on most outcome measures ([Van Ameringen et al. 2007](#)).

Trials with escitalopram have shown it to be superior to placebo in short-term, long-term, and relapse prevention

studies of generalized SAD ([Kasper et al. 2005](#); [Lader et al. 2004](#); [Montgomery et al. 2005](#)). Venlafaxine XR has also shown superiority over placebo in two double-blind trials of generalized SAD ([Allgulander et al. 2004](#); [Liebowitz et al. 2005](#)).

A double-blind, placebo-controlled trial of mirtazapine in women showed statistically significant superiority for drug over placebo ([Muehlbacher et al. 2005](#)). However, a more recent double-blind, placebo-controlled trial in 60 outpatients with generalized SAD who received mirtazapine at dosages of 30–45 mg/day failed to find evidence of efficacy ([Schutters et al. 2010](#)).

Paroxetine, paroxetine CR, sertraline, fluvoxamine CR, and venlafaxine XR are currently FDA approved for SAD treatment.

## **Benzodiazepines**

Three major placebo-controlled trials have shown efficacy for benzodiazepines in SAD. [Gelernter et al. \(1991\)](#) showed a modest effect for alprazolam over placebo (38% vs. 20% response rate) at a mean daily dosage of 4.2 mg, although it was generally inferior to phenelzine. [Davidson et al. \(1993\)](#) found a substantial 70% clonazepam response rate compared with a 20% placebo response rate in 75 subjects. Bromazepam was also found to be more effective than placebo ([Versiani et al. 1997](#)). A recent double-blind, placebo-controlled trial of augmentation and switch strategies for refractory SAD found that clonazepam augmentation of sertraline treatment (up to 3 mg/day) was superior to placebo augmentation and also to a switch to venlafaxine, with a higher percentage of patients achieving remission ([Pollack et al. 2014](#)).

Benzodiazepines provide significant benefits yet are not considered first-line drugs because of their more limited spectrum of action and potential withdrawal difficulties. However, they work rapidly, are well tolerated, and may be particularly useful for individuals with periodic performance-related social anxiety or treatment-resistant SAD.

## **Anticonvulsants**

Gabapentin and pregabalin produce significant effects in SAD. [Pande et al. \(1999b\)](#) found a superior effect for gabapentin over placebo in a trial using flexible dosing (ranging from 900 mg/day to 3,600 mg/day, with 2,100 mg/day being the most common final gabapentin dosage), with response rates of 39% and 17%, respectively. Baseline symptom scores were comparatively high and overall response rates relatively low, suggesting a degree of treatment-resistant illness in the study population. Pregabalin also has shown benefit in generalized SAD ([Feltner et al. 2003](#); [Pande et al. 2003](#)). Although pregabalin at a dosage of 150 mg/day was no different from placebo, 600 mg/day produced greater effects than placebo, with response rates of 43% and 22%, respectively. A 26-week double-blind, placebo-controlled maintenance trial of pregabalin at a fixed dosage of 450 mg/day showed that pregabalin not only was superior to placebo in maintaining symptomatic improvement but also was relatively well tolerated ([Greist et al. 2011](#)). Levetiracetam failed to differentiate from placebo ([Stein et al. 2010](#)). Further work with anticonvulsants is needed, given that these agents are generally well tolerated, safe, and less likely to produce discontinuation symptoms compared with many SSRIs and benzodiazepines.

## Reversible Inhibitors of Monoamine Oxidase A

Moclobemide is safer than older MAOIs and was shown to be almost as effective as phenelzine and significantly better than placebo ([Versiani et al. 1992](#)). However, subsequent studies did not support these findings ([Noyes et al. 1997](#); [Schneier et al. 1998](#)). The [International Multicenter Clinical Trial Group on Moclobemide in Social Phobia \(1997\)](#) found a modestly greater response rate (47%) for moclobemide at 600 mg/day than for placebo (34%). Moclobemide is approved in some countries but is not available in the United States. Another RIMA, brofaromine, has shown promise in three trials, with response rates of 78%, 50%, and 73%, respectively, compared with placebo response rates of 23%, 19%, and 0% ([Fahlén et al. 1995](#); [Lott et al. 1997](#); [van Vliet et al. 1992](#)), but it also is not marketed in the United States.

## Irreversible Inhibitors of Monoamine Oxidase

Phenelzine showed positive benefit in four studies ([Gelernter et al. 1991](#); [Heimberg et al. 1998](#); [Liebowitz et al. 1992](#); [Versiani et al. 1992](#)). Rates of response to phenelzine were 69%, 85%, 64%, and 65%, respectively, as compared with response rates of 20%, 15%, 23%, and 33% to placebo, and phenelzine overall has been shown to have a strong effect size ([Davis et al. 2014](#)). Even though phenelzine is consistently effective, its poor tolerability and risks make it unsuitable except for patients who have been nonresponsive to other treatments and who can adhere to the necessary dietary and medication restrictions.

## Other Drugs

Olanzapine yielded greater improvement than placebo in a small ( $n=12$ ) double-blind, placebo-controlled monotherapy trial ([Barnett et al. 2002](#)), suggesting that atypical antipsychotics may deserve further investigation in SAD, although their benefits will need to be weighed against their potential metabolic effects. Ondansetron, while producing a statistically significant effect relative to placebo, seems to be of limited clinical benefit ([Bell and DeVeaugh-Geiss 1994](#); [Davidson et al. 1997b](#)), although it may be used adjunctively in some cases. Buspirone was ineffective in a double-blind trial, with a 7% response rate ([van Vliet et al. 1997](#)).

Despite their intuitive appeal,  $\beta$ -blockers have shown poor effect in treating generalized SAD. For example, atenolol failed to separate from placebo in two trials ([Liebowitz et al. 1992](#); [Turner et al. 1994](#)).  $\beta$ -Blockers do show some value in performance-related social anxiety, perhaps by virtue of their ability to reduce peripheral autonomic arousal and block negative feedback. A double-blind trial of mirtazapine failed to show benefit ([Schutters et al. 2010](#)). Nefazodone, bupropion, and selegiline have not shown impressive results in open-label reports ([Emmanuel et al. 1991](#); [Simpson et al. 1998](#); [Van Ameringen et al. 1999](#)).

A novel therapeutic approach is suggested by the findings of [Hofmann et al. \(2006\)](#), who administered a single dose of D-cycloserine or placebo to patients with social anxiety disorder treated with CBT. The drug was given prior to each CBT session and enhanced the benefit of CBT to a greater extent than did placebo. The postulated mechanism of action relates to drug-facilitated extinction of learned fear via glutamatergic pathways. However, a recent placebo-controlled multisite trial of CBT augmentation with D-cycloserine in generalized SAD by the same authors found

that although D-cycloserine augmentation was associated with approximately a 30% faster rate of improvement, there was no difference in response or remission rate compared with placebo ([Hofmann et al. 2013](#)).

A study comparing the neurokinin-1 antagonist GR205171 against citalopram and placebo in 36 social phobia patients found response rates of 41.7%, 50%, and 8.3%, respectively, as well as a significant reduction in regional cerebral blood flow (rCBF) in the rhinal cortex, amygdala, and parahippocampal-hippocampal regions during a stressful public speaking task with the active agents ([Furmark et al. 2005](#)).

[Connor et al. \(2006\)](#) reported benefit for one-time intradermal bilateral axillary injections of 50 units of botulinum toxin type A for subjects with SAD and troublesome axillary hyperhidrosis. Effects persisted over 8 weeks and were superior to those of placebo for sweating, daily function, and activities. All subjects received concomitant paroxetine for other aspects of SAD.

## Treatment in Children and Adolescents

One placebo-controlled trial of fluvoxamine in children ages 6–17 years showed that it was superior to placebo in SAD, generalized anxiety disorder (GAD), and the combination: 76% of the fluvoxamine group responded, as compared with 19% of the placebo group ([Research Unit on Pediatric Psychopharmacology Anxiety Study Group 2001](#)). Double-blind trials of immediate-release (IR) paroxetine ([Wagner et al. 2004](#)) and venlafaxine XR ([March et al. 2007](#)) have

produced positive results in children and adolescents with generalized SAD.

A multisite trial in 488 children (ages 7–17 years) with a primary diagnosis of separation anxiety disorder, GAD, or SAD compared CBT alone, sertraline alone, combination CBT and sertraline, and placebo. CBT monotherapy and sertraline monotherapy were each superior to placebo in reducing anxiety symptoms in children (59.7% and 54.9% response rate, respectively); however, the combination treatment had the best response rate (80.7%) ([Walkup et al. 2008](#)). At follow-ups at 24 and 36 weeks, the majority of acute responders maintained their response, and the combination treatment maintained its advantage over the CBT and sertraline monotherapies ([Piacentini et al. 2014](#)).

## Duration of Treatment

SAD is a chronic illness, and treatment is generally recommended for years. [Sutherland et al. \(1996\)](#) reported that at 2-year follow-up, subjects who had received an active drug rather than placebo were doing better. Relatively few relapse prevention studies have been done. In a 12-month trial with clonazepam, [Connor et al. \(1998\)](#) showed a 20% relapse rate in those switched to placebo, compared with 0% in those who continued taking clonazepam. [Stein et al. \(1996\)](#) reported that 62% of the subjects relapsed when switched double-blind from paroxetine to placebo after 12 weeks, compared with only 12% who relapsed during maintenance treatment with paroxetine.

## Other Issues

CBT is efficacious in SAD, being comparable to pharmacotherapy ([Davidson et al. 2004b](#); [Fedoroff and Taylor 2001](#)), but little is known as to whether adding CBT to medication lowers the relapse rate, and so far the limited evidence does not suggest any potentiating effects when the treatments are combined ([Davidson et al. 2004b](#)), except in children ([Walkup et al. 2008](#)). In a comparative study of drug and psychotherapy, [Heimberg et al. \(1998\)](#) showed that phenelzine and CBT were approximately similar, although phenelzine had an edge in more severely symptomatic patients. On the other hand, when subjects who had discontinued treatment were followed up, rates of relapse tended to be lower in those who had received CBT than in those who had taken phenelzine. A later study by the same group ([Blanco et al. 2010](#)) showed superior outcomes for combined phenelzine and CBT over each treatment given alone.

---

## Specific Phobia

---

Specific phobia is among the most common psychiatric disorders, with a lifetime prevalence of 8%–12.5% ([Alonso et al. 2004](#); [Kessler et al. 2005b](#)) and 12-month prevalence of 3.5%–9% ([Alonso et al. 2004](#); [Kessler et al. 2005a](#)). Although the disorder is characterized by an early onset (median age at onset is 7 years) ([Kessler et al. 2005b](#)), most individuals are unimpaired by their symptoms and rarely seek treatment ([Magee et al. 1996](#); [Stinson et al. 2007](#); [Zimmerman and Mattia 2000](#)). However, for a minority of

individuals, specific phobia causes significant disability and requires treatment. The generally accepted treatment of choice is exposure therapy, which is uniformly and rapidly effective, with techniques including virtual reality as well as in vivo exposure and muscle tension exercises (for blood-injury phobia) ([Swinson et al. 2006](#)). Few studies have evaluated the efficacy of pharmacological approaches, and no drug has yet been approved by the FDA for treating specific phobia. No standard ratings exist for this disorder, although the Marks-Mathews FQ is quite suitable for blood-injury phobia and some other fears. A modification of this scale, the Marks-Sheehan Main Phobia Severity Scale (MSMPSS; [Sheehan 1986](#)), can be recommended.

Serotonergic drugs have shown efficacy in treating symptoms of fear and avoidance in a variety of anxiety disorders and thus would seem logical choices in specific phobias. In a small ( $n=11$ ) 4-week double-blind controlled trial, subjects receiving paroxetine (up to 20 mg/day) showed a 60% response rate, compared with 17% for subjects receiving placebo ([Benjamin et al. 2000](#)). A more recent randomized double-blind pilot trial compared escitalopram versus placebo over 12 weeks in 12 adults with specific phobia ([Alamy et al. 2008](#)). No difference was observed on the primary outcome; however, 60% of escitalopram-treated subjects showed response (based on a Clinical Global Impression Scale [CGI] Improvement score of 1 or 2), compared with 29% of subjects receiving placebo (effect size=1.13). The findings from these two small trials require validation in larger controlled trials. In contrast, in a controlled trial of the serotonergic and noradrenergic TCA imipramine in 218 phobic subjects (agoraphobic, mixed phobic, or simple phobic) receiving 26 weeks of

behavior therapy, no difference was observed between imipramine and placebo ([Zitrin et al. 1983](#)).

In a long-term controlled study of clonazepam in social phobia, [Davidson et al. \(1994\)](#) observed that clonazepam was superior in reducing symptoms of anxiety related to blood-injury phobia as measured by changes in the blood-injury phobia subscale of the Marks-Mathews FQ. Intermittent use of benzodiazepines also may be helpful in the acute treatment of the somatic anxiety that accompanies specific phobia, although this usage has not been an area of active investigation.

Using a novel approach, [Ressler et al. \(2004\)](#) investigated the effect of a cognitive enhancer, D-cycloserine, as an adjunct to psychotherapy. D-Cycloserine is an *N*-methyl-D-aspartate (NMDA) receptor partial agonist that has demonstrated improvement in extinction in rodents. Subjects with acrophobia ( $n=28$ ) were randomly assigned to receive a single dose of D-cycloserine or placebo prior to each of two virtual reality exposure therapy sessions. The combination of D-cycloserine and exposure therapy was associated with greater improvement in the virtual reality setting, as well as on a variety of anxiety domains. These changes were noted early in treatment and were maintained at 3-month follow-up. A recent small ( $n=35$ ) double-blind, placebo-controlled randomized trial of D-cycloserine enhancement of prolonged exposure therapy in dog- or spider-phobic children showed that D-cycloserine helped children to better retain their fear extinction learning ([Byrne et al. 2015](#)).

Specific phobia tends to be a chronic condition. Although psychotherapeutic approaches can be beneficial in the short term, evidence suggests that the initial gains noted

with treatment may not be sustained over the long term ([Lipsitz et al. 1999](#)). Pharmacological augmentation may help to extend the benefits of exposure therapy over time.

---

## Generalized Anxiety Disorder

---

GAD is a common disorder, with a lifetime prevalence of 5%–6% ([Wittchen and Hoyer 2001](#)), and is the most prevalent anxiety disorder in primary care, with rates that exceed 8% (Goldberg and Lecrubier [1995](#)). GAD tends to be a chronic and disabling condition with lifetime rates of comorbidity as high as 90% ([Blanco et al. 2014](#)), particularly depression (prevalence rate greater than 60%), which can increase the severity and burden of the disorder. Unlike prevalences of other anxiety disorders, GAD prevalence tends to increase with age, with a lifetime prevalence of 11% in individuals older than 65 years and late-life onset occurring in at least 25% of cases ([Zhang et al. 2014](#)).

Assessment of response in almost all GAD pharmacotherapy trials has been with the clinician-administered Hamilton Anxiety Scale (Ham-A; [Hamilton 1959](#)), which measures psychic and somatic symptoms of anxiety; remission is usually defined as a Ham-A score of 7 or less. The self-rated Hospital Anxiety and Depression Scale (HADS; [Zigmond and Snaith 1983](#)) is also widely used and is capable of detecting differences in treatment efficacy.

## Anxiolytics

## Benzodiazepines

Benzodiazepines have been widely used to treat acute and chronic anxiety since their introduction in the 1960s. Their activity is mediated through potentiation of the inhibitory neurotransmitter  $\gamma$ -aminobutyric acid (GABA) at the GABA<sub>A</sub> receptor. The efficacy and relative safety of benzodiazepines in short-term use (i.e., several weeks or months) are well established ([Rickels et al. 1983](#); [Shader and Greenblatt 1993](#)). However, the longer-term use of these drugs is more controversial and can be associated with the development of tolerance, physiological dependence, and withdrawal (if abruptly discontinued), as well as troublesome side effects, including ataxia, sedation, motor dysfunction, and cognitive impairment. Furthermore, these drugs should be avoided in patients with a history of substance use disorders, and long-term use may infrequently lead to the development of major depression ([Lydiard et al. 1987](#)).

Benzodiazepines have been shown to be effective in GAD, as reported by [Rickels et al. \(1993\)](#). The appeal of these drugs lies in their rapid onset of action, ease of use, tolerability, and relative safety. Findings from several 6- to 8-month trials of maintenance treatment for chronic anxiety have indicated continued efficacy of benzodiazepines over time ([Rickels et al. 1983, 1988a, 1988b](#); [Schweizer et al. 1993](#)). Because GAD tends to be a chronic disorder, many patients may need to continue pharmacotherapy with benzodiazepines (or other drugs) for many years, and long-term use of benzodiazepines may lead to the complications listed above.

Approximately 70% of patients with GAD will respond to an adequate trial of a benzodiazepine ([Greenblatt et al.](#)

1983), which corresponds to the equivalent of a 3- to 4-week treatment course of up to 40 mg/day of diazepam or 4 mg/day of alprazolam (Schweizer and Rickels 1996). Discontinuation should be managed by slow taper to minimize withdrawal symptoms, rebound anxiety, and relapse potential. Some evidence suggests that benzodiazepines may be more effective in treating the autonomic arousal and somatic symptoms of GAD but less effective for the psychic symptoms of worry and irritability (Rickels et al. 1982; Rosenbaum et al. 1984).

As our understanding of the phenomenology of GAD has grown, there has been a greater emphasis on the psychic component of the disorder (DSM-5; American Psychiatric Association 2013). Given these changes, along with the high rates of comorbid depression in GAD and the anxiolytic activity of many of the newer classes of antidepressants, the use of benzodiazepines as a primary treatment for GAD is less recommended.

## Azapirones

The azapirones are believed to exert their anxiolytic effect through partial agonism of 5-HT<sub>1A</sub> receptors. Several trials have indicated that buspirone is superior to placebo and comparable to benzodiazepines in treating GAD, with fewer side effects and without concerns for abuse, dependence, and withdrawal (Cohn et al. 1986; Enkelmann 1991; Petracca et al. 1990; Rickels et al. 1988b; Strand et al. 1990), although other studies have reported conflicting results (Fontaine et al. 1987; Olajide and Lader 1987; Ross and Matas 1987). Buspirone appears to be more effective in treating the psychic component of anxiety (Rickels et al. 1982), and possibly anxiety with mixed depressive

symptoms ([Rickels et al. 1991](#)), than in treating the somatic and autonomic symptoms of anxiety ([Schweizer and Rickels 1988](#); [Sheehan et al. 1990](#)). An adequate trial of buspirone in GAD would be 3–4 weeks of treatment at a dosage of up to 60 mg/day, in divided doses. Treatment-limiting effects of the drug include greater potential for side effects at higher dosages, slower onset of action, more variable antidepressant effects, and possibly reduced effectiveness in patients with a prior favorable response to benzodiazepines ([Schweizer et al. 1986](#)).

## Tricyclic Antidepressants

In a 6-week trial comparing imipramine and alprazolam, similar improvement was observed with both treatments by week 2; however, imipramine appeared to be more effective in treating the psychic anxiety component, whereas alprazolam was more effective in attenuating somatic symptoms ([Hoehn-Saric et al. 1988](#)). In an 8-week double-blind, placebo-controlled trial of imipramine, trazodone, and diazepam ([Rickels et al. 1993](#)), diazepam showed an early-onset effect by week 2, primarily on somatic symptoms. Over the next 6 weeks, however, psychic anxiety symptoms were more responsive to the antidepressants. Overall, imipramine was more efficacious than diazepam, trazodone was comparable to diazepam, and all treatments were superior to placebo. In a controlled trial comparing imipramine, paroxetine, and 2'-chlorodesmethyldiazepam, early onset of action was again noted with the benzodiazepine by week 2, but overall greater improvement was noted with the antidepressants by week 4, especially in psychic symptoms ([Rocca et al. 1997](#)).

# Selective Serotonin Reuptake Inhibitors and Serotonin-Norepinephrine Reuptake Inhibitors

A number of SSRIs are effective in GAD. Paroxetine IR at 20–50 mg/day has been shown to be as effective as imipramine and more effective than 2'-chlordesmethyldiazepam ([Rocca et al. 1997](#)). Compared with placebo, a similar dosage range of paroxetine IR was associated with significant reduction in anxiety after 8 weeks of treatment ([Bellew et al. 2000](#); [Pollack et al. 2001](#); [Rickels et al. 2003](#)), with an improvement in Ham-A-rated psychic anxiety observed as early as 1 week after initiating treatment ([Pollack et al. 2001](#)). Paroxetine IR also improves social functioning in patients with GAD ([Bellew et al. 2000](#)).

Escitalopram was found to be superior to placebo in improving anxiety symptoms, disability, or quality of life in three 8-week trials at a dosage range of 10–20 mg/day dose range ([Davidson et al. 2004a](#); [Goodman et al. 2005](#)), and it was found to be equivalent to paroxetine IR in a 6-month trial ([Bielski et al. 2005](#)). In a larger placebo-controlled trial, escitalopram 10 mg/day was superior to paroxetine 20 mg/day, and escitalopram dosages of both 10 mg/day and 20 mg/day were superior to placebo ([Baldwin et al. 2006](#)). A relapse prevention study found that sustained treatment with escitalopram 20 mg/day up to 74 weeks reduced the relapse rate (19%) relative to placebo substitution (56%) ([Allgulander et al. 2006](#)).

Sertraline was demonstrated to be superior to placebo in GAD in a 12-week ([Allgulander et al. 2004](#)) and a 10-week ([Brawman-Mintzer et al. 2006](#)) double-blind, placebo-

controlled trial; sertraline was well tolerated and showed beneficial effects on Ham-A-rated psychic and somatic anxiety symptoms compared with placebo ([Dahl et al. 2005](#)).

Several placebo-controlled trials have confirmed the short-term efficacy of venlafaxine XR in GAD over 8 weeks on both psychic and somatic symptoms. In a trial of 365 adult outpatients treated with venlafaxine XR (75 mg/day or 150 mg/day), buspirone (30 mg/day), or placebo, the Ham-A-adjusted mean scores of the anxiety and tension items were significantly improved at both active drug dosages compared with placebo; venlafaxine XR was superior to buspirone on the HADS anxiety subscale ([Davidson et al. 1999](#)). In a second trial of 541 outpatients on either venlafaxine XR (37.5 mg/day, 75 mg/day, or 150 mg/day) or placebo ([Allgulander et al. 2001](#)), the venlafaxine 75 mg/day and 150 mg/day dosages showed superior efficacy compared with placebo on all primary outcome measures (with improvement in psychic anxiety noted earlier than somatic symptoms), whereas the 37.5 mg/day dosage was superior to placebo on only one measure (the Anxiety subscale of the HADS). In a third trial of fixed dosages (75 mg/day, 150 mg/day, and 225 mg/day) of venlafaxine XR ([Rickels et al. 2000](#)), venlafaxine XR was superior to placebo on all outcome measures, with the most robust effects observed at 225 mg/day. Venlafaxine XR significantly reduced psychic anxiety but not somatic symptoms.

Venlafaxine XR also has shown long-term efficacy in GAD. In two 6-month controlled trials of fixed (37.5 mg, 75 mg, or 150 mg/day) ([Allgulander et al. 2001](#)) and flexible (75–225 mg/day) ([Gelenberg et al. 2000](#)) dosages of venlafaxine XR, significant improvement in anxiety was observed as early as 1 week, and efficacy was sustained over the 28-week

treatment period. In the fixed-dosage study, the greatest effect was observed with the 150-mg/day dosage. Significant improvement in social functioning was noted at the two higher dosages by week 8 and was sustained over the 6 months of the trial.

Venlafaxine XR is also effective in treating GAD with comorbid depression ([Silverstone and Salinas 2001](#)). After 12 weeks of treatment with venlafaxine XR (75–225 mg/day), fluoxetine, or placebo, significant reduction was observed in both Ham-A-rated anxiety and Hamilton Rating Scale for Depression (Ham-D; [Hamilton 1960](#))-rated depression only in subjects receiving venlafaxine XR. The response was delayed somewhat in subjects with comorbid GAD and depression as compared with those with depression alone, suggesting that individuals with comorbidity may benefit from a longer course of treatment.

There is agreement that the goal of treatment is to achieve remission, (e.g., a final Ham-A score  $\leq 7$ ). Pooled analysis of data from the two long-term studies noted earlier ([Allgulander et al. 2001](#); [Gelenberg et al. 2000](#)) has determined that remission is attainable in GAD ([Meoni and Hackett 2000](#)). By 2 months, approximately 40% of those receiving venlafaxine responded to treatment, and 42% attained remission. By 6 months, the proportion of those in remission increased to almost 60%, whereas responders declined to 20%, in contrast to a remission rate of less than 40% with placebo.

Venlafaxine XR has some advantages over the benzodiazepines—notably, antidepressant activity, lack of potential for abuse and dependence, and efficacy in treating symptoms of psychic anxiety. Nonetheless, venlafaxine can be associated with some adverse effects in the long term, including sexual dysfunction and blood

pressure elevation in some patients. Abrupt discontinuation of treatment can be associated with unpleasant side effects, most commonly dizziness, light-headedness, tinnitus, nausea, vomiting, and loss of appetite, and the discontinuation syndrome is worse if one abruptly stops at higher dosage levels ([Allgulander et al. 2001](#)).

Duloxetine, another SNRI antidepressant, has shown efficacy superior to placebo in GAD ([Allgulander et al. 2007](#); [Rynn et al. 2008](#)) in the range of 60–120 mg/day and also appears to lessen the chance of relapse during maintenance therapy. A recent randomized, placebo-controlled, flexible-dose study demonstrated that duloxetine was effective and well tolerated in the treatment of GAD in children and adolescents ages 7–17 years ([Strawn et al. 2015](#)).

One interesting application of SSRIs in GAD is in combination with nonbenzodiazepine hypnotics such as eszopiclone ([Pollack et al. 2008a](#)) and zolpidem ([Fava et al. 2009](#)), which may be particularly suited where insomnia is a major problem.

## Noradrenergic and Specific Serotonergic Antidepressants (Mirtazapine, Bupropion)

The antidepressant mirtazapine also has demonstrated anxiolytic properties ([Ribeiro et al. 2001](#)). However, published reports of its effect in GAD are limited to a small open-label study in major depression and comorbid GAD ([Goodnick et al. 1999](#)) and a small open-label GAD trial in 44 outpatients ([Gambi et al. 2005](#)). Although the results

were encouraging, data from controlled trials are needed to adequately assess a possible role for mirtazapine in GAD.

A 12-week double-blind active comparison trial of bupropion extended-release at 150–300 mg/day versus escitalopram at 10–20 mg/day in 24 subjects found similar Ham-A-rated anxiolytic efficacy of bupropion extended-release and escitalopram ([Bystritsky et al. 2008](#)). Notwithstanding these intriguing findings, the current body of clinical evidence supports the use of SSRIs or SNRIs before agents that are primarily noradrenergic in action.

## Hydroxyzine

Hydroxyzine blocks histamine<sub>1</sub> (H<sub>1</sub>) and muscarinic receptors. In three controlled trials, hydroxyzine was superior to placebo ([Ferreri and Hantouche 1998](#); [Lader and Scotto 1998](#); [Llorca et al. 2002](#)). Recent reports of hydroxyzine-related ventricular arrhythmias have led to cautionary labeling in Europe in the use of this drug and restriction of the maximum dosage to 100 mg/day ([European Medicines Agency 2015](#)).

## Anticonvulsants

The  $\alpha_2\delta$  calcium channel antagonist pregabalin was superior to placebo in four studies of GAD ([Feltner et al. 2003](#); [Pande et al. 2003](#); [Pohl et al. 2005](#); [Rickels et al. 2005](#)). Efficacy was noted early in treatment, but the ability of this drug to successfully treat some of the comorbid disorders associated with GAD is unknown. A recent review of six short-term double-blind, placebo-controlled pregabalin trials in GAD showed that pregabalin treatment

significantly improved both psychic and somatic Ham-A-rated GAD symptoms, with a dose-response effect that plateaued at 300 mg/day ([Lydiard et al. 2010](#)). Pregabalin has shown efficacy and reasonably good tolerability in elderly patients with GAD ([Montgomery 2006](#)). In a long-term trial in 624 GAD patients, responders to 8 weeks of open-label pregabalin at 450 mg/day were randomly assigned to receive pregabalin or placebo for 24 weeks ([Feltner et al. 2008](#)). Relapse rates were significantly lower for pregabalin (42%) than for placebo (65%), although attrition rates for pregabalin were higher (21.4% vs. 15.3%).

The GABA reuptake inhibitor tiagabine failed to separate from placebo on key measures in three placebo-controlled multicenter trials ([Pollack et al. 2008b](#)).

## Antipsychotics

Evidence for antipsychotic monotherapy in GAD is limited for some agents and more robust for others. An open-label trial suggested benefit for ziprasidone ([Snyderman et al. 2005](#)). Flupenthixol is approved for the treatment of depression in some countries and was shown in one controlled study to be superior to amitriptyline, clonazepam, and placebo in subjects with refractory GAD ([Wurthmann et al. 1995](#)). Sulpiride is also used in similar situations ([Bruscky et al. 1974](#); [Chen et al. 1994](#)).

The strongest evidence supporting atypical antipsychotic use in GAD at present is for quetiapine XR, which was shown to be effective and superior to placebo in a multicenter trial, and at 150 mg/day was effective for both psychic and somatic anxiety symptoms, with improvement

being noted as early as 4 days ([Bandelow et al. 2010](#)). The active comparator in this trial, paroxetine 20 mg/day, showed a lesser effect on somatic anxiety and a higher prevalence of sexual side effects. Remission rates were 42.6%, 38.8%, and 27.2% for quetiapine XR, paroxetine, and placebo, respectively. A longer-term double-blind, placebo-controlled multicenter maintenance trial with quetiapine XR at 50–300 mg/day in 432 patients found it to be effective in preventing recurrence of anxiety symptoms ([Katzman et al. 2011](#)).

Long-term use of atypical antipsychotics carries some concerns about tolerability and safety, especially in regard to weight gain and metabolic adverse effects, and these concerns need to be balanced against the long-term benefits in GAD in terms of reduction of disability and improved functionality.

## Other Drugs

Riluzole, a presynaptic glutamate release inhibitor, showed promise in a small open-label study at a daily dosage of 100 mg ([Mathew et al. 2005](#)).

Agomelatine, a serotonin 5-HT<sub>2C</sub> antagonist and melatonin<sub>1/2</sub> receptor agonist, is efficacious in GAD ([Stein et al. 2008](#)).

Complementary treatments have had mixed results in GAD. Homeopathy was found to be ineffective in one trial ([Bonne et al. 2003](#)). The herbal remedy kava did not separate from placebo in one trial ([Connor and Davidson 2002](#)), although [Sarris et al. \(2009\)](#) showed some evidence supporting the benefit of a water-soluble formulation of kava in subjects with short-term GAD-like symptoms. Liver

damage remains a potentially devastating concern, however, and even the preferred aqueous extract cannot be regarded as entirely safe, particularly at kava dosages above 250 mg/day ([Teschke and Schulze 2010](#)). Two small placebo-controlled trials suggested that chamomile and *Ginkgo biloba* may have modest anxiolytic effects in patients with mild to moderate GAD ([Amsterdam et al. 2009](#); [Woelk et al. 2007](#)). [Kasper et al. \(2014\)](#) demonstrated that lavender oil extract at dosages of 80 mg/day and 160 mg/day was superior to placebo and was better tolerated than paroxetine in a four-arm trial of subjects with DSM-5 GAD. Later studies by these researchers showed that the compound reduced 5-HT<sub>1A</sub> receptor binding in the hippocampus, anterior cingulate cortex, and fusiform and temporal gyri.

A meta-analysis of GAD studies by [Hidalgo et al. \(2007\)](#) showed that the effect sizes (in diminishing order from strongest to weakest) for each drug or drug group versus placebo were as follows: pregabalin, 0.50; hydroxyzine, 0.45; venlafaxine XR, 0.42; benzodiazepines, 0.38; SSRIs, 0.36; buspirone, 0.17; and homeopathy and herbal treatment, -0.31.

Drugs that have been approved in the United States for treating GAD or historical forerunners of the disorder include a large number of benzodiazepines, buspirone, paroxetine IR, escitalopram, venlafaxine XR, and duloxetine. Pregabalin is not approved in the United States but is approved for GAD in Europe.

There is also convincing evidence in favor of efficacy for CBT in GAD, with sustained benefit over 2 years of follow-up. These findings have been well reviewed by [Swinson et al. \(2006\)](#). There are no clinically informative studies to compare, or combine, CBT and pharmacotherapy in GAD,

but on pragmatic grounds, one may consider their combination in patients who have shown only a partial response to a thorough course of either CBT or medication alone.

---

## Obsessive-Compulsive Disorder

---

Although obsessive-compulsive disorder (OCD) has moved to a new disorder category—Obsessive-Compulsive and Related Disorders—in DSM-5, we have retained it in this chapter because of its similarities to anxiety disorders in presentation and treatment approaches.

According to the National Comorbidity Survey Replication (NCS-R), the lifetime and 12-month prevalence rates for OCD are 1.6% and 1.0%, respectively ([Kessler et al. 2005a, 2005b](#)). OCD has been recognized as the tenth leading cause of disability worldwide ([Murray and Lopez 1996](#)). Treatment can be grouped broadly into psychosocial and psychopharmacological approaches, the latter being our focus here. The chief rating scale for treatment studies of OCD remains the Yale-Brown Obsessive Compulsive Scale (Y-BOCS; [Goodman et al. 1989](#)), a 10-item observer-rated measure.

## Monotherapy

A series of placebo-controlled studies completed in the late 1980s and the early 1990s led to the first approved treatment of OCD in the United States and other countries ([Clomipramine Collaborative Study Group 1991](#)). Clomipramine is a potent serotonin reuptake inhibitor (SRI)

but is not selective for serotonin, because its demethylated metabolite is a norepinephrine reuptake inhibitor (NRI). The anti-OCD effect of clomipramine correlates with the plasma level of the SRI parent drug, suggesting that reuptake inhibition of serotonin is the critical factor underlying the drug's benefit. Moreover, selective noradrenergic reuptake inhibitors such as nortriptyline and desipramine have been shown to lack efficacy in OCD ([Leonard et al. 1988](#); [Thorén et al. 1980](#)).

In the [Clomipramine Collaborative Study Group \(1991\)](#) trial, the Y-BOCS score was reduced by about 40% in the active-drug group compared with a reduction of about 5% in the placebo group, consistent with findings by [Huppert et al. \(2004\)](#) that OCD has a remarkably low placebo response rate. Clomipramine and SSRIs are equivalent in the treatment of OCD ([Koran et al. 1996](#)); however, because of its side effects, clomipramine is considered a second-line treatment.

Today, SSRIs are considered the first-line treatment for OCD, and fluvoxamine, fluoxetine, sertraline, and paroxetine have been approved by the FDA for that indication ([Greist et al. 1995a, 1995b](#); [Tollefson et al. 1994](#)). Clomipramine, fluvoxamine, fluoxetine, and sertraline are also effective and indicated for treating OCD in children ([Flament et al. 1985](#); [Liebowitz et al. 2002](#); [March et al. 1998](#); [Riddle et al. 2001](#)), although CBT and the combination of CBT with an SSRI may be more effective ([Ivarsson et al. 2015](#)). When an SSRI drug is to be used in the treatment of OCD, it may need to be given at higher dosages, and it may take a longer time to work effectively ([Ninan et al. 2006](#); [Stein et al. 2007](#)). Most clinicians believe that treatment should be long-term to reduce the chance of relapse ([Pato et al. 1990](#)), although the dosage

might be lowered without loss of benefit ([Ravizza et al. 1996](#)).

## Long-Term Treatment and Relapse Prevention

Long-term pharmacological treatments of OCD have suggested sustained response beyond the acute treatment phase. In addition, clomipramine, paroxetine, sertraline, and escitalopram all have been shown to be more effective than placebo in prevention of OCD relapse ([Fineberg et al. 2005, 2007](#)). SSRIs appear to be well tolerated in these studies.

## Augmentation, Combination, and Other Strategies

Up to 60% of OCD patients show at least a partial response to SSRIs, although full remission is rare. Relapse can occur even during SSRI treatment, and comorbidity is common. The following augmentation, combination, and other novel strategies have been reported as offering benefit:

- The addition of fluvoxamine to clomipramine ([Szegeedi et al. 1996](#)) may be helpful for partial responders, as fluvoxamine inhibits clomipramine's demethylation, thus increasing the amount of available clomipramine and producing a potentiating effect. Monitoring of plasma levels and electrocardiograms is important with this combination to avoid toxicity and seizures.

- The use of intravenous clomipramine ([Fallon et al. 1992](#)) prevents first-pass metabolism, and side effects may be less severe. A double-blind trial of intravenous clomipramine suggested greater benefit with intravenous loading than with oral loading ([Koran et al. 1997](#)).
- In treatment-naïve (i.e., without refractory OCD) patients, the addition of quetiapine (moderate dosage) to high-dosage citalopram treatment was more effective than placebo augmentation ([Vulink et al. 2009](#)).
- The benzodiazepine clonazepam has been added to clomipramine treatment with mixed benefit ([Pigott et al. 1992](#)) and to sertraline treatment with no added benefit ([Crockett et al. 1999](#)).
- Patients with SRI-refractory OCD may benefit from antipsychotic augmentation. A meta-analysis demonstrated significant benefits for haloperidol and risperidone over placebo augmentation in OCD patients who failed to respond to an adequate SRI trial, whereas evidence for olanzapine and quetiapine was less robust ([Bloch et al. 2006](#)). However, quetiapine was superior to aripiprazole as an augmentation strategy in patients with OCD that was resistant to SRI treatment ([Shoja Shafiti and Kaviani 2015](#)).
- The addition of lithium, buspirone, desipramine, gabapentin, or ondansetron to SRIs has produced very limited benefits in studies to date, although there may be occasional patients for whom such combinations are helpful.
- Topiramate augmentation of maximum-dosage SSRI treatment in patients with treatment-refractory OCD had a beneficial effect on compulsions, but not obsessions, and was poorly tolerated ([Berlin et al. 2011](#)).

- One report suggested that St. John's wort (*Hypericum perforatum*) produced some improvement after 12 weeks of treatment in 12 patients with OCD ([Taylor and Kobak 2000](#)). However, a subsequent and adequately powered placebo-controlled study was negative ([Kobak et al. 2005](#)).
- Inositol, a naturally occurring second-messenger precursor, led to greater OCD symptom improvement than placebo at a dosage of 18 g/day for 6 weeks ([Fux et al. 1996](#)).
- Neurosurgical approaches (cingulotomy or anterior capsulotomy) can be helpful for refractory OCD. Between 25% and 50% of subjects show marked improvement, and the side-effect burden of this procedure is small ([Baer et al. 1995](#); [Jenike et al. 1991](#); [Pepper et al. 2015](#)).
- Small but promising studies also suggest benefits from deep brain stimulation for patients with treatment-refractory OCD ([Denys et al. 2010](#); [Greenberg et al. 2006](#); [Pepper et al. 2015](#)).
- rTMS studies have been limited in number of subjects and methodology and have yielded mixed results in patients with treatment-refractory OCD ([Mantovani et al. 2010](#); [Ruffini et al. 2009](#); [Sachdev et al. 2007](#); [Sarkhel et al. 2010](#)). A recent meta-analysis of rTMS augmentation of SSRI treatment in medication-resistant OCD showed positive results ([Ma and Shi 2014](#)).
- CBT is well established in the treatment of OCD, and evidence for its efficacy is strong, including as maintenance therapy ([Eddy et al. 2004](#); [Foa et al. 2005](#); [Peselow et al. 2015](#)). CBT employing exposure with response prevention is a first-choice option for OCD. One landmark study demonstrated that exposure with response prevention was superior to stress management

training as an augmentation strategy in clomipramine partial responders ([Simpson et al. 2008](#)).

---

## Posttraumatic Stress Disorder and Acute Stress Disorder

---

Although both posttraumatic stress disorder (PTSD) and acute stress disorder (ASD) were moved to a new disorder category—Trauma- and Stressor-Related Disorders—in DSM-5, we continue to include them in this review of anxiety-related conditions because of the similarities between their presentations, treatment interventions, and comorbid conditions and those of the anxiety disorders.

### Posttraumatic Stress Disorder

Posttraumatic stress disorder is a chronic and disabling disorder with a lifetime prevalence of about 7% ([Kessler et al. 2005a](#)). It can lead to significant functional impairment and inflict an enormous burden on society.

Treatment of PTSD must target the core symptoms of the disorder, focusing on improving resilience and quality of life and reducing comorbidity and disability. Widely used instruments (most of which are linked to DSM-IV [[American Psychiatric Association 1994](#)] criteria) include the Clinician-Administered PTSD Scale (CAPS; [Weathers et al. 2001](#)) and the more globally oriented Short PTSD Rating Instrument (SPRINT; [Connor and Davidson 2001](#)). Self-rating scales include the Davidson Trauma Scale (DTS; [Davidson et al. 1997a](#)), the PTSD Checklist (PCL; [Weathers et al. 1991](#)),

and the SPRINT, which also has been validated as a self-rating. DSM-5 ([American Psychiatric Association 2013](#))-based instruments (e.g., CAPS, PCL) have been developed and are in the process of being validated.

## Antidepressants

The TCAs and MAOIs were among the first pharmacological agents studied in controlled trials of PTSD. More recently, several controlled multicenter trials have shown efficacy for the SSRIs and SNRIs. With the documented antidepressant and anxiolytic effects of these agents and the high rates of comorbid depression in PTSD ([Kessler et al. 1995](#)), antidepressants would seem a logical choice for PTSD treatment.
